SIR: For the psychiatrist who practices in a hospital setting a relatively new system of medical record keeping has been instituted at several psychiatric hospitals around the country. I am referring to the "Weed System" or problem-oriented record (1). The Georgia Regional Hospital at Atlanta (GRHA) is one of the first psychiatric hospitals in the United States to fully convert its record system to the problem-oriented approach. I would like to comment on the reactions of psychiatrists toward the Weed System at this hospital.

GRHA is a 500-bed inpatient facility that serves metropolitan Atlanta. It consists basically of nine inpatient units. Each unit has a multidisciplinary team of mental health professionals that directs the treatment of patients. In-service training is available at the hospital to familiarize all mental health professionals with the Weed System.

At GRHA the Weed System has now been in effect since August 1971. One of the main issues of concern is orienting the staff to chart their impressions regarding specific problems on each patient's problem list. At this point it appears that of all the mental health professionals, the psychiatrists are the most resistant to the problem-oriented approach. Reasons psychiatrists give as to why they do not chart according to the problems are as follows: 1) failure to remember to chart according to the Weed System; 2) it takes too much time; and 3) sometimes the progress notes, orders for medications, etc., do not coincide with any of the stated problems. Of all the mental health personnel at the hospital with whom I have discussed the Weed System only the psychiatrists voice complaints about problem-oriented record keeping.

No conclusions can be drawn at this point, but it appears that, at least at this hospital, the psychiatrist is most resistant to the problem-oriented record. If the Weed System becomes an accepted standard for mental health record keeping, psychiatrists will have to reorient themselves or face the possibility of being resistant to constructive change in the health care delivery system.

The Death of Lyndon B. Johnson

SIR: Mr. Johnson is dead. Already from television and other news resources a picture of mixed facts and feelings has emerged. Particularly notable was a rerun of one of Mr. Johnson's last public appearances at the Johnson Library when he was observed to inconspicuously take a pill (later identified as a coronary vasodilator) while continuing to talk on a subject of vital interest to him—racial equality. I did not see him do this on the initial showing but did recall the commentators' noting that Mr. Johnson had entertained more questions than his physicians would have liked.

What will be the psychological effects on the people of this country and the world? I can recall speculating and pondering with colleagues on the symbolic significance of his announcement that he would be stepping down from the Presidency like a death knell of a father who might have failed his children, some of whom were angry, critical, and accusatory. I wondered too what people thought of this man who returned to a life he loved and could let his hair grow long after an "awesome" job.

What will be the effects of his death that we will not see and that we will see, on our couches, in our offices, in our clinics, and on the streets? We know of the range of reactions, from depressions to psychoses, that follow in the wake of a public figure's death.

What will we see now?

BOOK REVIEWS

Perspectives in Neuropharmacology: A Tribute to Julius Axelrod, *edited by Solomon H. Snyder, M.D. New York, Oxford University Press, 1972, 404 pp., no price listed.*

Perspectives in Neuropharmacology is a collection of 12 research reports and reviews by students and colleagues of Julius Axelrod, the 1971 recipient of the Nobel Prize for physiology and medicine. The contributors are among the most distinguished investigators in many areas of biochemical neuropharmacology. This volume was conceived of prior to the announcement of the Nobel Prize, as a Festschrift to honor Dr. Axelrod at the 1971 meeting of the Federation of American Societies of Experimental Biology.

In it are to be found eight papers concerning the chief area of Axelrod's interests, the catecholamines and indoleamines, including studies on the synthesis, storage, and catabolism of catecholamines and indoleamines, the role of the sympathetic nervous system in hypertension and white adipose tissue, and chemical, surgical, and immunological methods for producing sympathectomy. Other reports cover the isolation of the presumptive cholinergic receptor of the Torpedo electric organ, the possible role of histamine as a brain neurotransmitter, the pharmacology of gamma-aminobutyric acid (GABA) as an inhibitory neurotransmitter at a variety of synapses, and the interaction of estrogens, progestational agents, and androgens with brain and the pituitary gland and their role in the control of ovulation.

The essays are, without exception, not intended for the casual student of neuropsychopharmacology. The format of each is usually a terse but comprehensive and masterful review of a broad field followed by enticing illustrations of the author's current research and his thoughts about future research directions. Only a handful of the readers of this journal would be comfortable with these articles, but a prior reading of a text such as Cooper, Bloom, and Roth's *The Biochemical Basis of Neuropharmacology* (1) might provide the necessary background.

To be able to follow the material in this volume would be very desirable for psychiatric clinicians who want to keep up with the basic research that underlies current concepts of the biological etiology of the major mental disorders and the mechanism of action of psychotropic drugs. For example, the amino acid tryptophane has been proposed as a treatment for depression, while 5-hydroxytryptophane has been reported to be of value in the treatment of schizophrenia. Many investigators have postulated that abnormalities in the metabolism of tryptophane or 5-hydroxytryptamine are the cause of affective disorders or schizophrenia. Wurtman and Fernstrom's article in the current volume on the role of tryptophane in the control of brain amine synthesis is an important new chapter in understanding how amine synthesis is controlled.

Thoenen's article on 6-hydroxydopamine will help in the critical evaluation of Stein's recent proposal that 6-hydroxydopamine is the endogenous toxin that causes schizophrenia and perhaps mania and depression as well. The article by Hertting and Suko and that by Glowinski present important new concepts and data that will assist the reader in evaluating current variants of the catecholamine hypothesis of affective disorders and the mode of action of antidepressant drugs. Glowinski's article also cites provocative new data that the long-term effects of phenothiazines on dopamine synthesis may be to inhibit synthesis; if this is true, it would raise serious questions about current theories relating the mechanism of action of the neuroleptic drugs to blockade of dopamine receptors in the mesolimbic region and other areas of the brain. Iversen's review of GABA will be of great value in critically evaluating Eugene Robert's recent hypothesis proposing abnormality in the function of the system that utilizes GABA as a neurotransmitter in some types of schizophrenia.

If psychiatry is to continue to be rooted in the neurosciences and the medical tradition and not become totally immersed in the attempted resolution of the symptoms of social breakdown by means increasingly prescribed by nonmedical agencies, then more attention must be paid *by psychiatrists* to the type of studies reported in this excellent volume.

Chicago, Ill.

Childhood Psychopathology, *edited by Saul I. Harrison, M.D., and John F. McDermott, M.D. New York, International Universities Press, 1972, 882 pp., $20.*

This book, which is modestly subtitled "An Anthology of Basic Readings," may not have been intended as a comprehensive text. Nonetheless, its usefulness equals or surpasses that of most other current textbooks of childhood psychopathology. It is excellent for several reasons: It encompasses a wide range of clinical entities, it presents a diversity of viewpoints, and its individual chapters (articles culled from the literature of the 1940s, 1950s, and early to mid-1960s) are well written, informative, and always thought provoking.

The unifying theme of this book is that developmental concepts and data are essential to understanding psychopathology in childhood. The contents are grouped into nine sections: Development, Developmental Disorders, Neurotic Disorders, Learning Disorders, Antisocial Disorders, Psychophysiologic Disorders, Childhood Psychosis, Mental Retardation, and Brain Dysfunction. Many old favorites will delight the reader, including such classics as "Eight Ages of Man" by Erikson, "Hospitalism" by Spitz, "Underlying Causes of Delinquency" by Aichhorn, "Early Infantile Autism" by Kanner and Lesser, and "Effects of Adoption on Children from Institutions" by Skeels, to name only a few. While one might question the temerity of any editor who would attempt to encompass Piaget within the confines of two short chapters, the article titled "The Stages of the Intellectual Development of the Child" by Piaget is about as neat a presentation of the clinically relevant aspects of Piagetian cognitive theory as I have seen to date. It should

certainly stimulate the reader to investigate Piaget's writings in greater detail if he has not already done so.

The usefulness of the book has been enhanced by inclusion of a comprehensive subject index.

Childhood Psychopathology can be recommended to psychiatric teachers as a source of background readings for seminars and courses and to experienced clinicians who wish to have a collection of the "oldies and goodies" conveniently on their bookshelf. It can also be recommended to trainees, with one important caveat. The trainee who uses this text must be prepared to expand his understanding of the various topics by consulting recent review articles such as can be located through the *Bibliography of Medical Reviews* (1), published annually by the National Library of Medicine. While Harrison and McDermott have provided introductory and interstitial commentaries of a perceptive nature, these do not always bring the reader fully up-to-date. There are all too few references to articles published since 1966, so on the subject of early infantile autism, for instance, the student could be left with the impression that environmental factors play a primary role in the development of this syndrome, a concept that would be seriously at variance with recent literature on the subject.

There is an added bonus for all who purchase this text. Given that most of its selections have withstood the test of time, the shelf life of *Childhood Psychopathology* should be at least double or triple that of most textbooks.

PETER E. TANGUAY, M.D.
Los Angeles, Calif.

Psychiatric Diagnosis in New York and London: A Comparative Study of Mental Hospital Admissions, *by J.E. Cooper, D.P.M., R.E. Kendell, M.D., D.P.M., B.J. Gurland, D.P.M., L. Sharpe, M.B., D.P.M., J.R.M. Copeland, D.P.M., and R. Simon, M.A. Institute of Psychiatry, Maudsley Monographs, no. 20. New York, Oxford University Press, 1972, 145 pp., $12.50.*

This investigation, which was carried out under the aegis of a distinguished group, deserves worldwide attention from those concerned with a better understanding of psychiatric illness. The project's aim was to elucidate the reason for the differences between the diagnostic statistics that had been noted between the United States and Great Britain and to determine whether these variations were due to differences in the clinical characteristics of the patients or to differences in the diagnostic criteria used by the psychiatrists. After a survey of the common pitfalls in making comparisons of psychiatric illness in different areas, a research design was critically formulated and perceptively carried out.

In the first part of the study a comparison was made of 250 patients, aged 20 to 59, in each of two hospitals representative of their groups—a state hospital in New York and an English area hospital. A further comparison was made between 192 patients drawn from the nine state hospitals used by New York City and 174 patients from nine area hospitals in London.

Every patient was examined shortly after admission by a project psychiatrist and, independently, by a hospital psychiatrist. Mental state and history interviews and diagnostic criteria were standardized for the project teams, who trained together for several weeks in the use of the methodology. Periodic exchange of staff between New York and London kept the two teams in constant contact. Testing of consistency indicated a satisfactory reliability among the project psychiatrists.

There were striking differences in the incidence of diagnoses made by the hospital psychiatrists in the two cities. The most important difference was the higher incidence of schizophrenia in New York. This was due to the fact that the American concept of this illness is broader than it is in England, so that many patients diagnosed as having schizophrenia by American hospital psychiatrists would be considered by the British to have depressive illness, neuroses, personality disorders, or mania. In contrast, comparisons of the diagnoses by the project psychiatrists indicated that if the alcoholics and drug addicts, who were much more common in New York than in London, were omitted from both series and the remaining patients compared, there were no longer any significant differences. Instead, there was such a remarkable similarity that the diagnostic distributions of the patients entering the hospital in the two cities were, to all intents and purposes, identical.

It is concluded that the large, consistent differences between American and British hospital diagnostic statistics are largely spurious. The wide variation in use of terms, not only between countries but between sections of a country and even between hospitals within a small area, is also discussed. A plea for a universal, standardized system of patient examination and criteria for classification of psychiatric illness is convincingly presented. Only with uniformity will we be able to communicate more effectively in regard to our clinical findings and research. Agreement on terminology also will have broad implications for testing current etiological theories, whether they be social, psychological, or genetic.

HERBERT S. RIPLEY, M.D.
Seattle, Wash.

Modern Synopsis of *Comprehensive Textbook of Psychiatry,* by *Alfred M. Freedman, M.D., Harold I. Kaplan, M.D., and Benjamin J. Sadock, M.D. Baltimore, Williams & Wilkins Co., 1972, 800 pp., £15.95 (paper).*

Six years ago Freedman and Kaplan edited one of the most comprehensive textbooks of psychiatry ever published in this country (1). The present volume, listed as a "modern synopsis" of the king-size 1967 book, is not a breezy summary but is actually of sufficient dimension to present psychiatry in the round. It is not offered as a how-to-do-it manual. Thus it includes an interesting and reasonably in-depth historical background to almost every topic presented. There is something here on communication theory, the psychological basis of emotional disorders, anthropologic and sociologic factors in emotional disorders, the use of computers in psychiatry, and diverse theories of personality and psychopathology.

The book is rather heavily illustrated—an unusual feature in a psychiatric text, since the subject doesn't usually lend itself to pictures. One wonders, indeed, whether some of the illustrations are worth the space; and it is difficult to see how they contribute to the learning experience of the medical student or psychiatric resident.

The usual clinical syndromes are presented concisely and, in many chapters, rather leanly. For example, in this 800-page book, only 37 pages are allotted to the chapter on the neuroses. The book covers a wide arena, including an extensive section on child psychiatry (with an ingenious chart comparing *DSM-I* [2] with the current *DSM-II* [3] and some thoughts on community psychiatry, geriatrics, the possibilities and methods of

preventing mental illness, on retardation, and psychiatric emergencies.

In the net, this shapes up as a handy volume. Although it is aimed at medical students and residents, it is also a usable work for psychiatric practitioners. What it lacks in not offering the crispness of the ABC blueprint it makes up for in providing the reader with thought-provoking material that really does illustrate the breadth and depth of our specialty.

Psychology in Medicine, *by J.E. Orme, Ph.D., and F.G. Spear, M.D., D.P.M. Baltimore, Williams & Wilkins Co. (U.S. publisher), 1972, 211 pp., no price listed (paper).*

Jointly written by a clinical psychologist and a psychiatrist, this book is intended as an overview of psychological facts that will be useful to the physician, the medical student, and the psychology student in the early stages of graduate training. It seeks to scan a variety of psychological theories, techniques, and research findings, but with a greater practical emphasis than is found in the conventional introductory psychology textbook. The material presented is often tied to psychopathology, somatic phenomena, and diagnostic issues.

A number of the chapters are introduced within the framework of specific kinds of questions the psychiatrist is likely to ask of the psychologist when referring a patient for psychological testing. There are descriptions of the state of the art with reference to using psychological tests to evaluate intellectual functioning, the presence of brain damage, personality pathology, and trait attributes. The writers are English, and so they slant their discussions of psychological tests in the direction of those presently most popular in English circles. This may be a good corrective experience for those of us who live in the United States and tend to become provincially invested in our own native techniques.

Succinct descriptions are also provided of some of the major therapeutic approaches. There are reviews of behavior, group, suggestion, and physical therapies. These descriptions are direct and factual. They exemplify the excellent, no-nonsense level of communication that characterizes this book throughout. What comes through in all of the presentations is the intent to be fair and to avoid extreme positions. There is skepticism about pure clinical intuition but also sympathy for the complex problems facing the clinician.

Incidentally, an appendix is included that summarizes a number of the major techniques useful in experimental design and statistical analyses.

The authors appraise recurrent problems that exist in the collaboration between psychiatrist and psychologist. They probe traditional areas of rivalry. For example, they refer to the nagging dispute about whether the psychologist is as qualified as the psychiatrist to take full responsibility for treatment. They consider areas in which the psychologist's training may better prepare him for taking on certain tasks, such as evaluation and management of the retarded or the planning of clinical research projects. They caution the psychiatrist to curb his inclination to regard the psychologist as an auxiliary technician. But they point out, too, that the psychologist is tempted to be snobbish about his greater "scientific" training. Overall, their discussion is balanced and contains useful hints about how the two disciplines can maximize their usefulness to each other.

The authors have successfully accomplished what they intended to do. One would expect the book to be especially useful in the teaching of medical students and psychiatric residents. Indeed, anyone who is interested in a broad informative sweep of what is presently known about the clinical applications of psychology will find it worthwhile.

SEYMOUR FISHER, PH.D.
Syracuse, N.Y.

Theory and Practice of Family Psychiatry, *by John G. Howells, M.D., D.P.M. New York, Brunner/Mazel, 1971, 924pp., $25.*

This impressive compendium starts out with the statement by the editor that individual psychiatry is replaced by family psychiatry, that is, individuals are not "functioning units." Despite this sweeping introduction, Dr. Howells makes a major contribution, and a balanced one, in outlining and defining the field, and he by no means ignores the individual dimension.

The first 100 pages, and over one-tenth of the volume, are written entirely by Dr. Howells; they represent a comprehensive review of basic concepts, family dynamics, and social parameters concerning the family as well as the clinical practice of family psychiatry.

The second part, a further presentation of the same issues and problems by other authors, moves from considerations of the individual to relationships to group property and community actions. There are also chapters on material aspects of family life, again by Dr. Howells. These are republications spanning almost 20 years.

The third and last part illustrates the clinical practice of family psychiatry beginning with Howells' description of his own service and a chapter on an assessment by his collaborator, J.R. Lickorish. The rest of this section is a collection of previously published papers on clinical syndromes and therapy, except for two original papers by Spiegel and by Virginia Satir.

It is difficult to render a critical appraisal of this volume as a whole because any collection of about 50 papers by different authors must necessarily be of varying value and significance. On the whole, I could not quarrel with any particular selection, and I know of very few that were omitted or might have been included instead of some others.

It is convenient to have in one volume so many of the basic papers in the field. Included in the book are some classic contributions such as Spelt's on intrauterine conditioning, Greenacre's on the parent-infant relationship, D. Levy's study of hostility, Henry and Warson's ethological family study, Hilgard and Newman's anniversary classic, the model study of Lasko on first and second children, and Norman Bell's essay on boundaries.

Dr. Howells' own contributions are of great importance and an admirable guide to those who wish to engage in family research or become family psychotherapists. The only regrettably weak chapter is that by Lickorish, which not only reflects the uncertain methodological state of family assessment, but fails to refer to other significant efforts at such assessments, some of which are included in this volume.

Unfortunately, such a volume quickly becomes dated; and despite the erudition of Dr. Howells' chapters on the dimen-

sions of family psychiatry, more recent concepts, for instance a general systems approach, are lacking.

C. Sager's introduction to the American edition is excellent and emphasizes that family psychiatry is basic to community psychiatry..

STEPHEN FLECK, M.D.
New Haven, Conn.

Shame and Guilt in Neurosis, *by Helen B. Lewis, Ph.D. New York, International Universities Press, 1971, 525 pp., $15.*

For the sake of criticism this work had best be divided into three sections. These divisions are mine, not the author's. The first and longest of these sections deals exhaustively (and sometimes exhaustingly) with various definitions, explications, and discussions of the concepts of shame and guilt. These include dictionary definitions from *Webster's* and the *Oxford English Dictionary* and the working definitions of a large number of authors who have previously written on the subject. A thorough review is made of the theories of Freud and later psychoanalysts concerning the formation of the superego structure. Strangely, little mention is made of specific kinds of parental influence that seem, to me, to foster predominance of one or the other of these complex and painful affects.

Instead, the author turns to the differentiation construct of Witkin. In this, perceptual style is measured by such methods as the rod and frame test and the embedded figure test, and ratings are made as to the degrees of field dependence and field independence. By comparing normals and clinically ill patients, Witkin and his colleagues have felt that there is definite evidence of congruence between the subject's test performance, perceptual style, personality variables other than perceptive ones, and his clinical picture: "Low self-esteem and high need for approval are characteristics which have been linked to field dependence" (p. 165).

After a discussion of the methodology the author reports a series of experiments in which patients were rated as field independent or field dependent and then were interviewed. The interview transcripts were then rated for implied verbal affect by the method of Gottschalk and Glaser, and it was shown that there were significant differences in amounts of shame and guilt affects communicated. Field-dependent patients demonstrated a preponderance of shame, while field-independent patients demonstrated more guilt. Field-dependent patients were prone to direct hostility against themselves, while field-independent patients directed their hostility outward.

In the second section the author turns to microanalysis of the patients' productions in therapy and to patient-therapist interaction. Through this examination come chapters dealing with "The Phenomenology of Shame," "The Phenomenology of By-Passed Shame," "The Phenomenology of Guilt," "Shame in the Transference," and so forth. The therapy transcripts are excellent, interesting, and sensitive and demonstrate clearly that if a therapist is alert to the manifestations of shame and guilt concealed within therapeutic communication, a new dimension can be added to understanding.

The last section contains a review of Freud's case material regarding the role of shame and symptom formation. Added to this are several case reports from the author's own therapeutic experience. In these, the author attempts to link symptom formation with shame and guilt in the patient's remote past, recent past, and in the transference. She connects these with Freud's classic statement of symptoms resulting from "strangulated affects."

The author concludes that there are intrinsic advantages in the phenomenological stance toward shame and guilt in therapy in that this stance prevents the analyst from being caught up in the patient's obsessive ruminations and also makes it easier not to take sides or be judgmental about issues in the patient's life. She seems to have demonstrated this reasonably.

The first section of the book will be of considerable interest to the experimenter in affect seeking a review of previous work done in this line. This section will be of less interest to the clinician but may spur him into an attempt at clinical research design. The second and third sections will hold more interest for the clinician in their depiction of therapeutic exchange between therapists and patients of widely different perceptual style. The bibliography is excellent, but a glaring fault is the absence of an index.

MAURICE J. BARRY, JR., M.D.
Rochester, Minn.

A Guide to Behavioral Analysis and Therapy, *by Robert Paul Liberman, M.D. Elmsford, N.Y., Pergamon Press, 1972, 339 pp., $5.50 (paper).*

The last decade has seen a rapid growth of the clinical and experimental literature relating to behavior therapy (the systematic application of principles of learning to the analysis and treatment of disorders of behavior). Several excellent textbooks have been published that acquaint the clinician with this approach to assessment and provide him with a comprehensive survey of behavior therapy procedures.

The present book has a different focus. While being technically accurate, it presupposes that the reader has virtually no formal knowledge of psychiatry or clinical psychology. Hence it will be especially useful for acquainting nurses, psychiatric aides, and other workers in the mental health field with this approach to psychiatry. It will also serve as a useful introduction for psychiatrists and psychologists with no previous knowledge of behavior therapy who want a brief overview of the field. Appetite whetted, the initiated clinician might want to read heartier fare elsewhere—an annotated bibliography is provided in the book for this purpose.

The first part of the book introduces the language and methods of behavior therapy. Terms and concepts that are basic to a behavioral approach are systematically developed in the context of illustrative case material. These include such notions as reinforcement, extinction, shaping, satiation, and generalization. The reader is given practice in this section in making a psychiatric assessment in terms of specific, observable, quantifiable behavior rather than the more traditional emphasis on conflicts and personality traits.

The second part of the book describes specific behavior therapy procedures. Although only a few are given, the choices are good since they include procedures of wide application that convey the range of problems currently treated by behavior therapy. There are chapters on systematic desensitization, assertive training, the use of token economy procedures with institutionalized patients, behavioral techniques in family therapy, the treatment of schizophrenic children, and operant techniques for the improvement of children's classroom performance.

The semiprogrammed style of the presentation is both effective and instructive. Since programmed instruction makes use of several behavioral principles (e.g., shaping and reinforcement), the reader has a first-hand behavior modification experience in proceeding through the volume.

In sum, this brief book should be a useful introduction to be-

havior analysis and therapy for a wide audience of workers in the mental health field.

JOHN PAUL BRADY, M.D.
Philadelphia, Pa.

Marital Therapy: Moral, Sociological and Psychological Factors, *edited by Hirsch Lazaar Silverman, Ph.D., Sc.D., L.H.D., LL.D. Springfield, Ill., Charles C Thomas, 1972, 527 pp., $24.75.*

It was a pleasure to review this well-edited collection of essays by a selected group of 47 contributors, many of whom are well known for their previous contributions in this field. Our patients are presenting themselves more and more with family and marital problems. Thus an awareness of the moral, sociological, and psychological factors in marriage becomes mandatory. This book consists of 43 chapters (to be referred to after this by numbers in parentheses) and is subdivided into four sections: psychological, sociological, moral, and finally, an evaluation of each chapter by the editor. There are extensive biographical notes on each of the contributors at the beginning of the book.

Many of the essays in this book fill a gap in the literature concerned with the prevention of marital problems. The first chapter, by Mary S. Calderone, and the concluding chapter, by Sister M. Catherine deRicci Killeen, both deal with sex education. Both authors stress that when we fail to attend to our children's emotional growth, we will have to worry how various stimuli may affect them. Their answer, and the answer of many of the authors in this book, is education—in the home, in the educational systems, and in religious and secular institutions. In a thoughtful essay (chapter 10) Thomas McGinnis categorizes the various organized and unorganized groups that oppose sex education and their reasons for doing so. He offers guidelines to communities on how to assess their individual situations. Ira L. Reiss (18) gives an excellent presentation of his great concern about the current direction of sex education in schools.

Robert J. Goodstein (26) provides insights, which have preventive value, into the typology of girls who are prone to premarital pregnancy. Donald D. Moore (4) coordinates the lack of sex education and unpractical morality. Patricia Schiller (22) cogently deals with her preventive efforts with teen-age pregnancies. Joseph B. Trainer (3) offers five specific ways to prevent marital problems. William F. Eastman and Clifford R. Reifler (12) discuss their experiences within a university health service. David R. Mace (14) succinctly discusses a continuum of minimum to limited to maximum modes of interpersonal involvement in the ultimate goal of prevention with group sessions of couples with stable marriages. Gerald Sanctuary (29) of Great Britain presents the experiences, especially pertinent for mental health community centers, of the selection, basic training, and in-service training procedures of volunteer workers.

A wide spectrum of therapeutic frameworks is presented by the essayists, ranging from an eclectic, interpersonal, Bernean, Heideggerian ontological, and psychoanalytic to group therapeutic setting. An interesting chapter by William L. Carrington (30) of Australia stresses five essential factors of morale necessary in counseling (marital vis-à-vis martial).

The editor's 16 chapters are devoted to sociological factors. David O. Moberg (20) beautifully presents the role of manipulation in both counseling and human behavior. Ethel M. Nash and A.E. Keir Nash (24) strongly stress the role of marriage counselors in coping with the gravity of the population explosion. (See Dr. A.B. Sabin's thought-provoking article in the October 1972 issue of the *Bulletin of the Atomic Scientists* [1].)

In the section on moral factors, clergymen and other essayists present careful deliberations that are important in the solution of marital disharmony. Professor Panos D. Bardis (15) presents an interdisciplinary, sociohistorical study of religion that combines description, theory, and quantification. Albert Ellis (5) presents his principles of morality as it pertains to relationships with others. In an excellent essay John G. Quesnell and the Reverend Paul Marx (33) discuss the basic problem facing the counselor who is working with a Catholic couple who wish to be true to their conscience, their faith, and the teachings of the encyclical *Of Human Life.*

I have found that experienced pastoral counselors are of great help when the couple wish to deal with their problem from a theological, rather than a psychiatric, point of reference. Space prevents a discussion of the other superb chapters.

This book will be a valuable addition to the library of the psychiatrist.

Winnetka, Ill.

Science and Psychoanalysis, vol. XIX: Dream Dynamics, *edited by Jules H. Masserman, M.D. New York, Grune & Stratton, 1971, 188 pp., $13.50.*

This book is a compilation of papers presented at the 19th annual meeting of the American Academy of Psychoanalysis; it is organized around dream function, meaning, and techniques of interpretation. The contributors represent a variety of disciplines, use diverse conceptual approaches, and differ markedly in writing style. Books emanating from symposia are always uneven in their quality of information and clarity of presentation, and this one is no exception.

The sections are titled Dream Thoughts and Theories, The Dreams of Childhood, Clinical Applications, and A Dream Symposium. If the reader, particularly the clinician, approached the book with a keen anticipation that it presented a unified theory of dreaming followed by a consistent, validated system of relating dream interpretation to the psychoanalytic or psychotherapeutic process, he would close its hard cover with a resolve to cling even more tenaciously to the reporting of phenomena emerging during the conscious state. There were sharp disagreements among the contributors, but this ferment revealed some changing views on the purpose of dreaming as well as techniques for the interpretation of dreams.

The understanding of dreams as covert expressions of instinctual drives organized by wish-defense considerations no longer holds as much currency as in the past. The continuum between waking and dreaming concerns and cognitive modes was pointed out by several contributors. Indeed, the manifest content of the dream was described as having a communicative language of its own and not as a code for disguised impulses in the latent content. The dream was also viewed as a continuation of problem-solving behavior present during the day.

This notion that dreams are disguised forms of communication and wish fulfillment was challenged most effectively by Beck. In a paper of brilliant clarity, he proposed that the cognitive style of waking life is used in the dream where the same basic themes are present, albeit metaphorically. For example, depressive themes of failure, defeat, and coercion are expressed in

a comparable manner in both waking and dreaming states. Spiegel and her discussant, Salzman, extended this proposition in a paper on the dreams of obsessional patients, where issues of control, doubting, and obfuscation are evident not only in the dream itself but also in the manner in which the patient dreams to neutralize and overwhelm a therapist through frequency of presentation, enormous detail of imagery, and contentious refusal to accept their significance as a valid statement of feelings. Salzman's guide to the management of dreams in the obsessional patient is almost worth the price of the book.

Of considerable interest is the report of a series of seminars on dream interpretation conducted under the aegis of the academy. It is a description of the group dynamics of individualistic analytic practitioners engaged in a scientific project requiring the exposure to critical assessment by colleagues of a particular aspect of what they do as therapists, as well as a searching examination of how dreams are interpreted and incorporated into ongoing analytic therapy. This chapter, written by three of the participants, was an open, honest, and courageous attempt to describe the frustration, conflict, divergence of opinion and approach, and failure to reach consensus by the group. The description of the dream as art and metaphor was meaningful, and the impression was conveyed that dream interpretation by analysts in a group is comparable to achieving harmonious assessment of an abstract canvas by a group of art critics. Indeed, Bonime expressed the idea that dream interpretation, rather than being the "royal road to the unconscious," is primarily a device by which the analyst trains the patient to structure personal data to conform to the therapist's personal and theoretical beliefs.

The book is in the tradition of this distinguished academy's prior published symposia. Established dogma is challenged and examined within the framework of information and theories provided by other disciplines. This book is well worth the nonanalytic psychiatrist's time.

ELLIOT D. LUBY, M.D.
Detroit, Mich.

Psychotropic Drugs in the Year 2000: Use by Normal Humans, *compiled and edited by Wayne O. Evans, Ph.D., and Nathan S. Kline, M.D. Springfield, Ill., Charles C Thomas, 1971, 158 pp., $7.75.*

The papers in this volume were presented at the annual meeting of the American College of Neuropsychopharmacology in 1967. The editors state that their aim in publishing them is to draw the attention of the public to the varieties of mind-affecting chemical substances that can be produced and to the many questions of responsibility that the creation and use of these substances involve. This modest goal is of course achieved.

However, the title of the book seems to promise something more. It suggests than an effort will be made to anticipate how the lives of normal individuals will be influenced by chemical substances in the future. This type of projection has value if it succeeds in identifying long-term trends that are lost sight of in the immediacy of short-term pressures or if it generates new concepts that can be used in directing our professional energies.

Few of the papers rise above unimaginative extrapolations of current clichés. Kline, the old master of the innovative breakthrough, does suggest a number of different and unconventional ways of influencing life. "It is not," he says, "equipment and techniques but conceptualizations which are really most basic to change." He offers as an aphorism, "Today's side effects are tomorrow's therapy." Heinz Lehmann, too, exhibits some originality in his discussion of the possible approaches to the alleviation of the hardships of old age.

The idea of using chemical substances to intensify and protract pleasurable sensations and to obliterate the anguish of daily life troubles me. Perhaps it is because I have made my peace with the current realities of life by considering disappointment and suffering likely, and pleasure an occasional respite. But I prefer to think that any change in the pain/pleasure ratio, in family life and social existence, cannot be considered apart from the influences it exerts upon that organization. Effective aphrodisiacs, it could be argued, can contribute as much to the reinforcement of the traditional marriage tie as to the promotion of adolescent promiscuity. But in practice how can we anticipate what its effect will be? And is not making sensuality rather than restraint the basis of social existence actually the idol worship of the Bible, which usually brings a prosperous civilization to its end?

All the writers seem to accept the principle that physicians are obligated to increase pleasure and alleviate distress. There is a real difference between this principle as a value and the value of healing the ill. Not all distress arises from illness, and a good measure of stress seems to be necessary for the vigor of every society and every species. Mr. John Campbell, editor of *Analog Science Fiction* and a discussion panelist at this meeting, is the only participant who takes notice of this.

Evans and Kline and a few others do assert that the serious problem of psychopharmacology concerns who should make the decisions to apply the agents, upon whom, and under what circumstances. Yet these statements lead to no serious consideration of the problem. Similarly, despite occasional notes that drugs which exert one desirable action may bring about compensatory and undesired reactions, this problem is not seriously considered.

Finally, I have yet to be persuaded that the effects of psychomimetic drugs are anything other than illusions born of drug delirium. I can accept the claim of Kurland, Pahnke, Unger, Savage, and Grof (in the only clinical paper in the volume) that controlled use of LSD in a therapeutic setting can alleviate anguish. But I have encountered no serious evidence that anything creative or constructive has been achieved. Many psychiatrists accept the claim of some of those who have used these drugs that they obtained "new knowledge" which can solve problems. Even our more conservative colleagues, such as those represented in this book, speak respectfully of these claims. I would like to see our profession take the more forthright stand that hallucinogenic drugs generate hallucinations and illusions. They can create euphorias of various qualities and temporary changes in personality, some of which may even be welcome. But their mode of action is disintegrating rather than integrating, and limiting rather than enriching.

This Month's Reviewers

HERBERT Y. MELTZER, M.D., is Associate Professor of Psychiatry at both the University of Chicago Pritzker School of Medicine and the Illinois State Psychiatric Institute, Chicago, Ill.

PETER E. TANGUAY, M.D., is Assistant Professor of Psychiatry (in Residence), Division of Child Psychiatry and Mental Retardation, Department of Psychiatry, University of California at Los Angeles Center for the Health Sciences, Los Angeles, Calif.

HERBERT S. RIPLEY, M.D., is Professor of Psychiatry, University of Washington School of Medicine, Seattle, Wash.

HENRY A. DAVIDSON, M.D., is Chief of Neurology and Psychiatry, New Jersey Office of the Veterans Administration, Trenton, N.J.

SEYMOUR FISHER, PH.D., is Professor, Department of Psychiatry, State University of New York, Upstate Medical Center, Syracuse, N.Y.

STEPHEN FLECK, M.D., is Professor of Psychiatry and Public Health, Yale University School of Medicine, New Haven, Conn.

MAURICE J. BARRY, JR., M.D., is Consultant in Psychiatry, Mayo Clinic, Rochester, Minn.

JOHN PAUL BRADY, M.D., is Professor of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, Pa.

BERNARD L. GREENE, M.D., is Clinical Professor of Psychiatry, Abraham Lincoln School of Medicine, University of Illinois Medical Center, Chicago, Ill., and Clinical Professor of Pastoral Psychology (Marital Problems), Garrett Theological Seminary, Evanston, Ill.

ELLIOT D. LUBY, M.D., is Professor of Psychiatry and Law, Wayne State University School of Medicine, Detroit, Mich.

MORTIMER OSTOW, M.D., is in private practice in Bronx, N.Y.

Books Received

This listing acknowledges the receipt of recent books. Books of particular interest to the readers of this journal will be reviewed as space permits, and copies of the reviews will be sent to the publishers. Books cannot be returned to the publishers.

Eidetic Parents Test and Analysis, *by Akhter Ahsen, Ph.D. New York, Brandon House, 1972, 246 pp., $17.50.*

Computer Glossary for Medical and Health Sciences, *by William T. Blessum, M.D., and Charles J. Sippl. New York, Funk & Wagnalls, 1973, 262 pp., $6.95.*

The Manipulator: A Psychoanalytic View, *by Ben Bursten, M.D. New Haven, Conn., Yale University Press, 1973, 267 pp., $10.*

Human Ageing, *edited by Sheila M. Chown. Baltimore, Penguin Books, 1973, 380 pp., $3.95 (paper).*

Community Mental Health: Social Action and Reaction, *edited by Bruce Denner and Richard H. Price. New York, Holt, Rinehart and Winston, 1973, 359 pp., no price listed (paper).*

The Psychoanalytic Study of the Child, vol. 27, *edited by Ruth S. Eissler, M.D., Anna Freud, LL.D., D.Sc., M.D., Marianne Kris, M.D., and Albert J. Solnit, M.D. New York, Quadrangle Books, 1973, 641 pp., $12.50.*

Handbook of Abnormal Psychology, 2nd ed., *edited by H.J. Eysenck, Ph.D., D.Sc. New York, Pitman Publishing Corp., 1973, 861 pp., £20.*

Zwang und Schizophrenie, *by Hans Feer. New York, S. Karger, 1973, 108 pp., $12.60 (paper).*

Try Being Human, *by Alec Forbes. Berkhamsted, Hertfordshire, England, Langdon Books, 1973, 89 pp., £1.80 (paper).*

Interviewing: Its Principles and Methods, 2nd ed., *by Annette Garrett, revised by Elinor P. Zaki and Margaret M. Mangold. New York, Family Service Association of America, 1972, 209 pp., $3.95 (paper).*

The School We Have, *by Shepard Ginandes, M.D. New York, Delacort Press/Seymour Lawrence, 1973, 273 pp., $7.95.*

Characteristics of NARA Patients in Aftercare During June 1971, *by Ron Gold and Lois R. Chatham, Ph.D. Rockville, Md., Narcotic Addict Rehabilitation Branch, Division of Narcotic Addiction and Drug Abuse, National Institute of Mental Health, 1973, 35 pp., no price listed (paper).*

Mental Development Evaluation of the Pediatric Patient, *by Lawrence C. Hartlage, Ph.D., and David G. Lucas, M.A. Springfield, Ill., Charles C Thomas, 1973, 75 pp., $6.50.*

Feminine Psychology, *by Karen Horney, M.D., edited by Harold Kelman, M.D. New York, W.W. Norton & Co., 1973, 258 pp., $2.95 (paper).*

Males and Females, *by Corinne Hutt. Baltimore, Penguin Books, 1973, 150 pp., $2.45 (paper).*

Out of the Closets: Voices of Gay Liberation, *edited by Karla Jay and Allen Young. New York, Overlord-Krishna & Schaffer, 1972, 403 pp., $7.95.*

Transcultural Psychiatry, *by Ari Kiev. Harmondsworth, Middlesex, England, Penguin Books, 1973, 240 pp., 75 p (paper).*

The Right To Be Different: Deviance and Enforced Therapy, *by Nicholas N. Kittrie. Baltimore, Penguin Books, 1973, 434 pp., $2.25 (paper).*

The Crisis Team: A Handbook for the Mental Health Professional, *by Julian Lieb, M.B., Ian I. Lipsitch, M.D., and Andrew Edmund Slaby, M.D. New York, Harper & Row, 1973, 177 pp., $6.96 (paper).*

Autogenic Therapy, vol. 6: Treatment with Autogenic Neutralization, *by Wolfgang Luthe, M.D. New York, Grune & Stratton, 1973, 425 pp., $9.75.*

Man & Woman, Boy & Girl: The Differentiation and Dimorphism of Gender Identity from Conception to Maturity, *by John Money and Anke A. Ehrhardt. Baltimore, Johns Hopkins Press, 1973, 292 pp., $12.50.*

Autobiography of a Thief, *by Andrew Keith Munro. Levittown, N.Y., Transatlantic Arts (U.S. distributor), 1973, 155 pp., no price listed.*

Getting There Without Drugs, *by Buryl Payne. New York, Viking Press, 1973, 204 pp., $7.95.*

The Collected Works of C.G. Jung, vol. 2: Experimental Researches. Bollingen Series XX, *edited by Sir Herbert Read, Michael Fordham, M.D., Gerhard Adler, Ph.D., and William McGuire, translated by Leopold Stein in collaboration with Diana Riviere. Princeton, N.J., Princeton University Press, 1973, 627 pp., $17.50.*

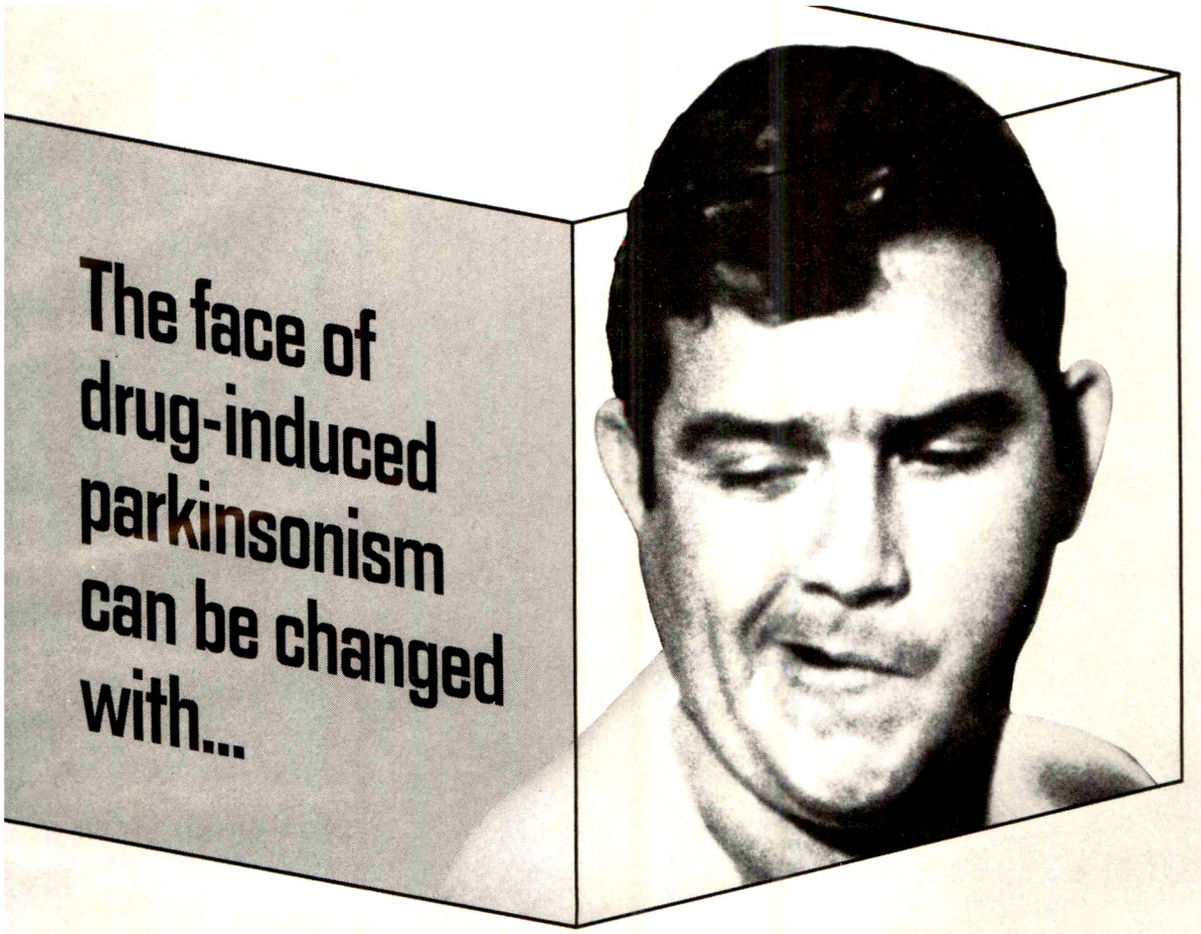
Man's Aggression: The Defense of the Self, *by Gregory Rochlin, M.D. Boston, Gambit, 1973, 287 pp., $8.95.*

Psychotherapy of Schizophrenia, *edited by David Rubinstein, M.D., and Yrjö O. Alanen, M.D. Amsterdam, Excerpta Medica, 1973, 338 pp., $29.*

Communicational Structure: Analysis of a Psychotherapy Transaction, *by Albert E. Scheflen, M.D. Bloomington, Indiana University Press, 1973, 378 pp., $15.*

Anger: Psychology, Physiology, Pathology, *by Frederic R. Stearns, M.D. Springfield, Ill., Charles C Thomas, 1973, 66 pp., $6.50.*

Principles of Human Genetics, 3rd ed., *by Curt Stern. San Francisco, W.H. Freeman and Co., 1973, 872 pp., $13.95.*



C.G. Jung, *by Anthony Storr. New York, Viking Press, 1973, 111 pp., $5.95.*

Clinical Studies in Psychiatry, *by Harry Stack Sullivan, M.D., edited by Helen Swick Perry, Mary Ladd Gawel, and Martha Gibbon. New York, W.W. Norton & Co., 1973, 378 pp., $3.65 (paper).*

A Primer of Misbehavior: An Introduction to Abnormal Psychology (reprint), *by George R. Wesley, Ph.D. Totowa, N.J., Littlefield, Adams & Co., 1973, 196 pp., $2.50 (paper).*

Atlas of the Massachusetts Department of Mental Health, 1972, *compiled and edited by Margo Withy. Boston, Mass., Department of Mental Health, 1973, 70 pp., no price listed (paper).*

Children of the Rich, *by Burton N. Wixen, M.D. New York, Crown Publishers, 1973, 209 pp., $5.95.*

AKINETON®
(biperiden)

- relieves extrapyramidal reactions
- reduces akinesia and rigidity
- combines well with other anti-parkinson agents
- more than ten years of clinical experience

WARNINGS, PRECAUTIONS, ADVERSE REACTIONS: Isolated instances of mental confusion, euphoria, agitation and disturbed behavior have been reported in susceptible patients. Use with caution in manifest glaucoma, prostatism and cardiac arrhythmia. Dry mouth, blurred vision and drowsiness appear infrequently. Some decrease in urinary flow has been noted in a few patients. If gastric irritation occurs, it may be avoided by administering during or after meals. With parenteral administration, mild transient postural hypotension may be evidenced. The only known contraindication is sensitivity to Akineton (biperiden.) DOSAGE: Orally: **Parkinsonism:** 1 tablet, 2 mg., 3 or 4 times daily. **Drug-induced extrapyramidal disorders:** 1 tablet, 2 mg., 1 to 3 times daily. Parenterally: the average adult dose is 2 mg. intramuscularly or intravenously. May be repeated every half-hour until resolution of symptoms is effected, but not more than 4 consecutive doses should be administered in a 24-hour period. SUPPLIED: Tablets—2 mg. (bisected) Akineton HCl. Ampules—1 ml. containing 5 mg. Akineton lactate in an aqueous 1.4% sodium lactate solution.

The challenge: versatility

The stereotype image of "psychiatrist and couch" is an anachronism because today's psychiatrist is called on to diagnose and treat depression in a variety of clinical settings. And when an antidepressant medication is chosen, it must be as flexible and as adaptable as the physician prescribing it.

The psychiatrist's office still represents the setting in which the psychoanalytic process recognizes its fullest potential. Frequently, however, an antidepressant must be employed to foster a working therapeutic relationship. With effective symptomatic relief often provided by ELAVIL® (Amitriptyline HCl, MSD), depressed patients may be able to concentrate on underlying factors instead of somatic manifestations.

The general hospital today usually provides a psychiatric unit where depressed patients are treated. Here, too, the symptomatic relief ELAVIL often provides can be a valuable part of total treatment. As depressive symptoms are relieved, for example, patients may take advantage of the therapeutic activities offered and, even more important, may be discharged sooner and treated on an outpatient basis.

In the outpatient clinic, where follow-up treatment may be necessary for three months or longer, ELAVIL is highly effective in maintaining relief, especially in patients who responded well to higher doses while hospitalized. As a result, these patients may continue to function in their daily activities.

In the mental hospital, severely depressed patients present challenges for psychiatrist and staff alike. Here, the usefulness of ELAVIL is increased by the 50-mg tablet that provides the higher doses often required and by the injectable form for more rapid effect.

The community mental health center, a remarkable innovation in the field of modern psychiatry, offers a unique setting for treating patients with clinically significant depression. Here, too, ELAVIL often proves to be a true asset to the psychiatrist by providing highly effective symptomatic relief that can encourage communication, support the psychotherapeutic relationship, and accelerate the achievement of desired therapeutic goals.

in the treatment of depression

TABLETS: 10 mg, 25 mg, and 50 mg INJECTION: 10 mg per ml

ELAVIL®

addendum

ELAVIL®
(AMITRIPTYLINE HCl | MSD)
dosage forms for differing patient needs

25 mg (yellow)

This tablet may prove useful for most outpatients, who generally do well on 25 mg three times a day. This dosage may be increased to a total of 150 mg a day. Dosage increases are made preferably in the late afternoon or at bedtime. The sedative effect may be apparent before the antidepressant effect is noted. An adequate therapeutic effect may take as long as 30 days to develop.

50 mg (beige)

The 50-mg tablet may be indicated whenever higher dosages are required, as for example when increases are necessary in the late afternoon or bedtime doses. It may also be convenient for many hospitalized patients who may need 100 mg a day initially. In these patients, dosage may be increased gradually to 200 mg a day if necessary. A small number of hospitalized patients may need as much as 300 mg a day.

10 mg (blue)

Because lower doses are generally recommended for adolescents and elderly patients, the 10-mg tablets may be most serviceable. Ten mg three times a day with 20 mg at bedtime may be satisfactory in adolescent and elderly patients who do not tolerate higher dosages.

INJECTION
10 mg per ml

For patients unable or unwilling to take tablets, the injectable form may be suitable initially. The tablets should replace the injection as soon as possible. Initial intramuscular dosage is 20 to 30 mg (2 to 3 ml) four times a day. When Injection ELAVIL is administered intramuscularly, the effects may appear more rapidly than with oral administration.

Usage in Children: In view of the lack of experience in children, this drug is not recommended at the present time for patients under 12 years of age.

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor or within at least 14 days following the discontinuance of a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction or for patients under 12 years of age.

Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or urinary retention, or with angle-closure glaucoma or increased intraocular pressure. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia, and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.

When given with anticholinergic agents or sympathomimetic drugs, close supervision and careful adjustment of dosages are required. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains during treatment and until significant remission occurs; this type of patient should not have easy access to large quantities of the drug. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: The intravenous administration of 1–3 mg of physostigmine salicylate has been reported to reverse the symptoms of amitriptyline poisoning.

How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

5 NEW BOOKS OF SPECIAL INTEREST IN PSYCHIATRY

☐ **ADDICTION: An Artificially Induced Drive** *by* **Nils Bejerot,** *Karolinska Institutet, Stockholm, Sweden. Foreword by* **S. S. B. Gilder.** Abuse of drugs may be a symptom of social or psychological maladjustment. Addiction is classified herein into single, epidemic, and endemic cases. Some principles of treatment and of attacking drug epidemics are discussed on the basis of these theories. Other important topics of interest are discussed. This text will be of special interest to those concerned with this problem. *'72, 96 pp., 8 il., 3 tables, $7.50*

☐ **RELIGIOUS EXPERIENCE: Its Nature and Function in the Human Psyche. The First John G. Finch Symposium on Psychology and Religion** *by* **Walter Houston Clark, H. Newton Malony, James Daane** *and* **Alan R. Tippett.** *Foreword by* **Lee Edward Travis.** The roots of religion are not in growths of church, belief, or ethics, but in religious experience. The text shows that properly directed, profound religious experiences are potent sources of personality change. References are made to case illustrations. *'72, 168 pp., 1 il., $7.95*

☐ **CRISIS CENTER/HOTLINE: A Guidebook to Beginning and Operating** *edited by* **Ursula Delworth, Edward H. Rudow** *and* **Janet Taub.** *All of Colorado State Univ., Fort Collins. Foreword by* **Western Morrill.** *(12 Contributors)* Presented in a general manner, providing useful information about the day-to-day operation of a crisis center. Insights and experiences by both professionals and volunteer students are included, thus providing a model for the inclusion of paraprofessionals in the mental health field. *'72, 160 pp., $9.75*

☐ **THE THEORY AND PRACTICE OF PSYCHOTHERAPY WITH SPECIFIC DISORDERS** *edited by* **Max Hammer,** *Univ. of Maine, Orono. (10 Contributors)* Provides psychotherapists with exposure to the newest and most effective approaches today. Case illustrations are amply and appropriately supplied. Areas rarely discussed in psychotherapy books are included. A chapter is devoted to establishing some basic criteria for an effective therapeutic process. Offers new interpretations and theoretical discussions. *'72, 464 pp., $16.75*

☐ **THE MECHANISMS OF CONDITIONED BEHAVIOR: A Critical Look at the Phenomena of Conditioning** *by* **Wanda Wyrwicka,** *Univ. of California, Los Angeles.* This study analyzes the well-known data as well as new findings in conditioning experiments and interprets them from a new point of view. The role of such factors in conditioning as time intervals, sequence of stimuli, permanent environmental features, and a possible mechanism of formation of the conditioned neural pattern are thoroughly discussed. *'72, 192 pp., 16 il., 2 tables, $11.50*

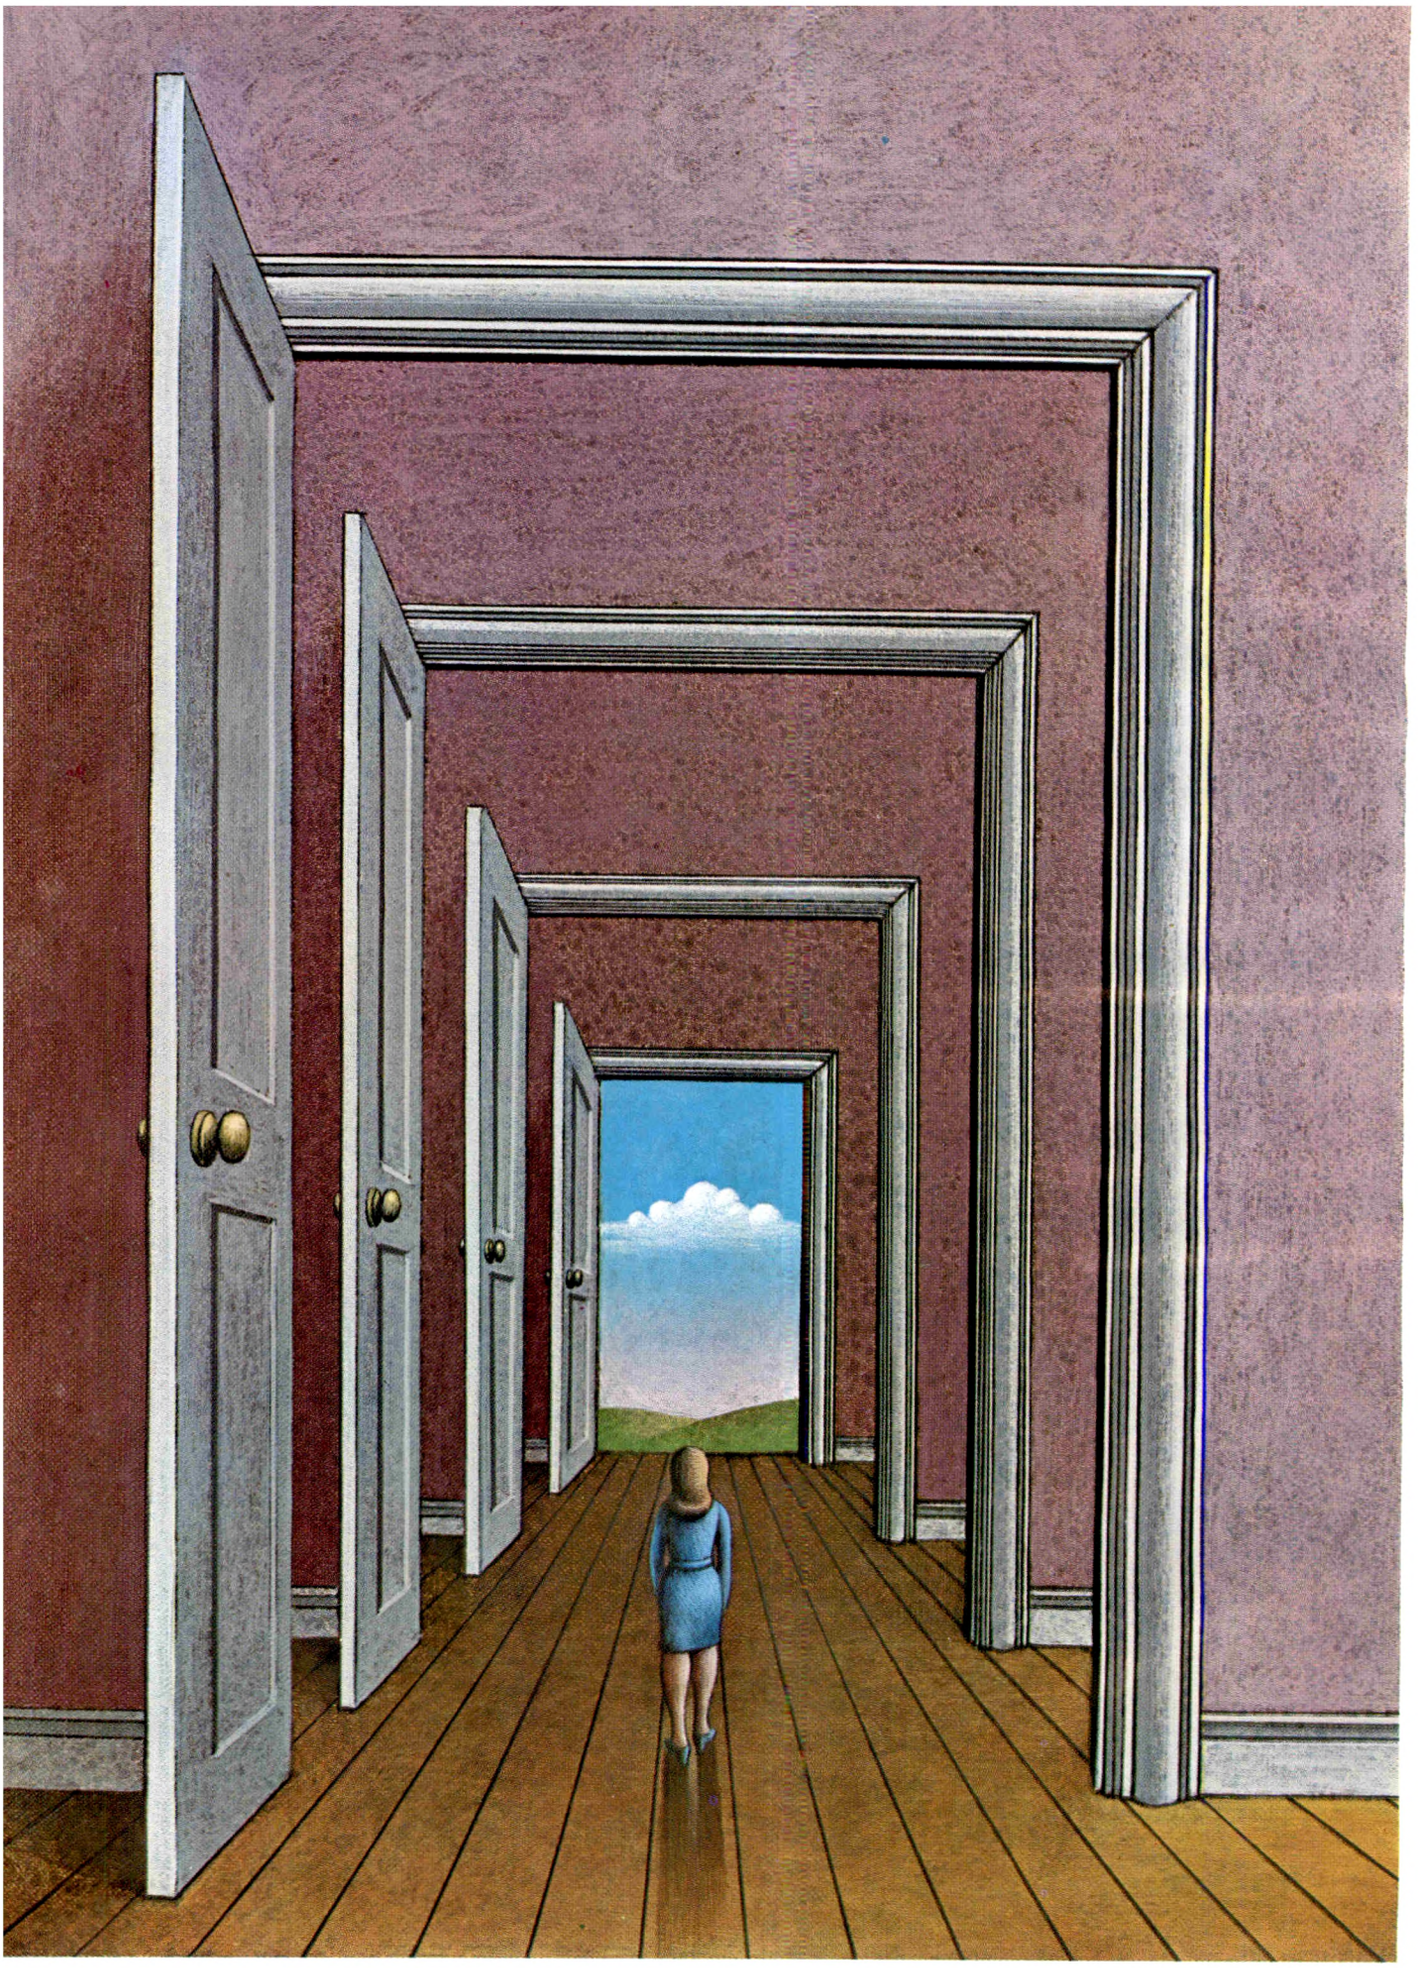
☐ **PRACTICAL PROBLEMS OF A PRIVATE PSYCHOTHERAPY PRACTICE** *compiled and edited by* **George D. Goldman** *and* **George Stricker,** *both of Adelphi Univ., Garden City, New York. (14 Contributors)* '72, 300 pp., 6 il., 3 tables, $11.50

☐ **MENTAL HEALTH SERVICES FOR THE MENTALLY RETARDED** *edited by* **Elias Katz,** *Univ. of California, San Francisco. (19 Contributors)* '72, 292 pp., 4 il., $12.75

☐ **DRUG ABUSE: Current Concepts and Research** *compiled and edited by* **Wolfram Keup,** *State Univ. of New York Downstate Medical Center, Brooklyn. (70 Contributors)* '72, 496 pp., 20 il., 93 tables, $19.50

☐ **PETS AND HUMAN DEVELOPMENT** *by* **Boris M. Levinson,** *Yeshiva Univ., New York.* '72, 256 pp., 13 tables, $10.50

☐ **EVALUATION AND MANAGEMENT OF THE VIOLENT PATIENT: Guidelines in the Hospital and Institution** *by* **John R. Lion,** *Univ. of Maryland School of Medicine, Baltimore.* '72, 88 pp., $6.00



☐ **THE GENETIC, METABOLIC AND DEVELOPMENTAL ASPECTS OF MENTAL RETARDATION** *edited by* **Robert F. Murray, Jr.** *and* **Pearl Lockhart Rosser,** *both of Howard Univ. College of Medicine, Washington, D. C. Foreword by* **Roland B. Scott.** *(26 Contributors)* '72, 366 pp., 65 il., 15 tables, $16.75

☐ **LAW, LANGUAGE AND COMMUNICATION** *by* **Walter Probert,** *Univ. of Florida, Gainesville. Foreword by* **Harold D. Lasswell.** '72, 408 pp., 10 tables, $13.50

☐ **THE LSD CONTROVERSY: An Overview** *by* **Maurice S. Tarshis,** *Formerly, Alcohol and Drug Section, Mental Health Division, State of Oregon. Foreword by* **Herman A. Dickel.** '72, 96 pp., 1 il., 2 tables, $6.50

☐ **UNDERSTANDING THROUGH COMMUNICATION: Structured Experiments in Self-Exploration** *by* **Lois Timmins,** *Timberlawn Psychiatric Hospital, Dallas. Foreword by* **Howard M. Burkett.** '72, 336 pp., $11.75

CHARLES C THOMAS • PUBLISHER 301-327 East Lawrence Avenue **SPRINGFIELD • ILLINOIS • 62717**

A HEAD START FOR THE CLINICALLY DEPRESSED PATIENT.

All tricyclic antidepressants take from one to four weeks before optimal antidepressant effect is seen.

Sinequan (doxepin HCl)—the newest tricyclic antidepressant—is no exception.

But, in that waiting period, Sinequan offers the clinically depressed patient both:

prompt sedative activity to begin relieving the sleep disturbances often characteristic of depression, and

marked antianxiety activity to help relieve the apprehension, tension, worry and fear that usually accompany depression.

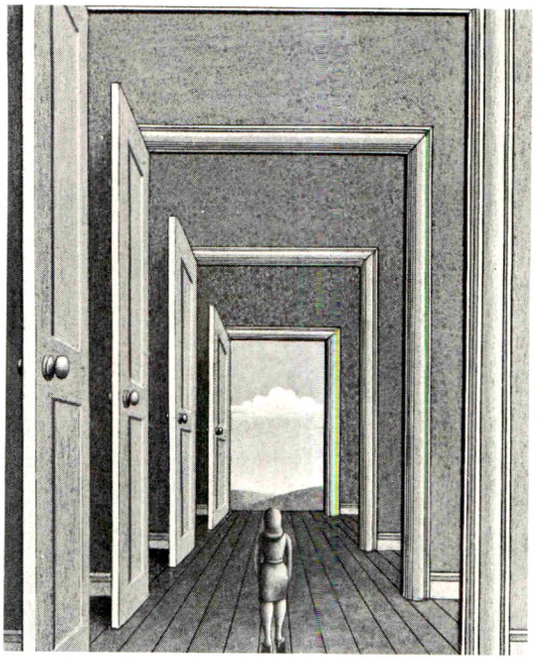
Further, the incidence of cardiovascular side effects with Sinequan is relatively low. Tachycardia and hypotension are infrequent. (Drowsiness is the most common side effect.) And Sinequan, unlike other tricyclic antidepressants, does not generally affect the activity of guanethidine and similarly acting compounds at usual clinical doses.

Prompt sedative activity. Marked antianxiety activity. Low incidence of cardiovascular side effects.

It's a head start for the clinically depressed patient.

THE NEWEST TRICYCLIC ANTIDEPRESSANT— WITH DIFFERENCES YOU CAN SEE.

Sinequan®
DOXEPIN HCl
25-mg. and 50-mg. capsules



Pfizer **LABORATORIES DIVISION**
PFIZER INC.

(See Brief Summary on following page for information on adverse reactions, contraindications, warnings and precautions.)

©1973, PFIZER INC.

Sinequan®
DOXEPIN HCl
25-mg. and 50-mg. capsules

THE NEWEST TRICYCLIC ANTIDEPRESSANT—WITH DIFFERENCES YOU CAN SEE.

BRIEF SUMMARY

Sinequan® (doxepin HCl) **Capsules**

Contraindications. Sinequan (doxepin HCl) is contraindicated in individuals who have shown hypersensitivity to the drug.

Sinequan (doxepin HCl) is contraindicated in patients with glaucoma or a tendency to urinary retention.

Warnings. *Usage in Pregnancy:* Sinequan (doxepin HCl) has not been studied in the pregnant patient. It should not be used in pregnant women unless, in the judgment of the physician, it is essential for the welfare of the patient, although animal reproductive studies have not resulted in any teratogenic effects.

Usage in Children: The use of Sinequan (doxepin HCl) in children under 12 years of age is not recommended, because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with Sinequan (doxepin HCl). The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered, and the dosage involved.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug.

Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy.

Although Sinequan (doxepin HCl) has significant tranquilizing activity, the possibility of activation of psychotic symptoms should be kept in mind.

Other structurally related psychotherapeutic agents (e.g., iminodibenzyls and dibenzocycloheptenes) are capable of blocking the effects of guanethidine and similarly acting compounds in both the animal and man. Sinequan (doxepin HCl), however, does not show this effect in animals. At the usual clinical dosage, 75 to 150 mg. per day, Sinequan (doxepin HCl) can be given concomitantly with guanethidine and related compounds without blocking the antihypertensive effect. At doses of 300 mg. per day or above, Sinequan (doxepin HCl) does exert a significant blocking effect. In addition, Sinequan (doxepin HCl) was similar to the other structurally related psychotherapeutic agents as regards its ability to potentiate norepinephrine response in the animal. However, in the human this effect was not seen. This is in agreement with the low incidence of the side effect of tachycardia seen clinically.

Adverse Reactions. *Anticholinergic Effects:* Dry mouth, blurred vision, and constipation have been reported. They are usually mild, and often subside with continued therapy or reduction of dose.

Central Nervous System Effects: Drowsiness has been observed. This usually occurs early in the course of treatment, and tends to disappear as therapy is continued.

Cardiovascular Effects: Tachycardia and hypotension have been reported infrequently.

Other infrequently reported side effects include extrapyramidal symptoms, gastrointestinal reactions, secretory effects such as increased sweating, weakness, dizziness, fatigue, weight gain, edema, paresthesias, flushing, chills, tinnitus, photophobia, decreased libido, rash, and pruritus.

Dosage. For most patients with illness of mild to moderate severity, a starting dose of 25 mg. t.i.d. is recommended. Dosage may subsequently be increased or decreased at appropriate intervals and according to individual response. The usual optimum dose range is 75 mg./day to 150 mg./day.

In more severely ill patients an initial dose of 50 mg. t.i.d. may be required with subsequent gradual increase to 300 mg./day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding a dose of 300 mg./day.

In patients with very mild symptomatology or emotional symptoms accompanying organic disease, lower doses may suffice. Some of these patients have been controlled on doses as low as 25-50 mg./day.

Although optimal antidepressant response may not be evident for two to three weeks, antianxiety activity is rapidly apparent.

Supply. Sinequan (doxepin HCl) is available as capsules containing doxepin HCl equivalent to 10 mg., 25 mg., and 50 mg. of doxepin in bottles of 100 and 1000.

HEL [illegible] THE [illegible] EAL IN REALITY

Effective Management of Psychotic Symptoms

- Calms hyperactive behavior
- Controls hostility
- Decreases delusions, auditory and visual hallucinations
- Allays underlying fear, anxiety and tension
- Lessens unusual thought content, paranoid ideation
- Reduces emotional withdrawal

Before prescribing, see complete prescribing information including dosage and symptoms and treatment of overdosage, in SK&F literature or *PDR*.

Indications
Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of manifestations of psychotic disorders.

Probably effective: For control of the manifestations of manic-depressive illness (manic phase). For the control of moderate to severe agitation, hyperactivity or aggressiveness in disturbed children.

Possibly effective: For control of excessive anxiety, tension and agitation as seen in neuroses.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose states, presence of large amounts of C.N.S. depressants, or bone marrow depression.

Warnings: Avoid using in patients hypersensitive (e.g., blood dyscrasia, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy. Avoid concomitant use with alcohol. May counteract antihypertensive effect of guanethidine and related compounds.

Use in pregnancy only when essential. There are reported instances of jaundice or prolonged extrapyramidal signs in newborn whose mothers had received chlorpromazine.

Precautions: Use cautiously in persons with cardiovascular, liver or chronic respiratory disease, or with acute respiratory infections. Due to cough reflex suppression, aspiration of vomitus is possible. May prolong or intensify the action of C.N.S. depressants, organophosphorus insecticides, heat, atropine and related drugs. (Reduce dosage of concomitant C.N.S. depressants.) Anticonvulsant action of barbiturates is not intensified. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Discontinue high-dose, long-term therapy gradually.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, cholestatic jaundice, agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura and pancytopenia; postural hypotension, tachycardia, fainting, dizziness and, occasionally, a shock-like condition; reversal of epinephrine effects; EKG changes have been reported, but relationship to myocardial damage is not confirmed; neuromuscular (extrapyramidal) reactions; pseudoparkinsonism, motor restlessness, dystonias, persistent tardive dyskinesia, hyperreflexia in the newborn; psychotic symptoms, catatonic-like states, cerebral edema; convulsive seizures; abnormality of the cerebrospinal fluid proteins; urticarial reactions and photosensitivity, exfoliative dermatitis, contact dermatitis; lactation and breast engorgement (in females on large doses), false positive pregnancy tests, amenorrhea, gynecomastia; hyperglycemia, hypoglycemia, glycosuria; dry mouth, nasal congestion, constipation, adynamic ileus, urinary retention, miosis, mydriasis; after prolonged substantial doses, skin pigmentation, epithelial keratopathy, lenticular and corneal deposits and pigmentary retinopathy, visual impairment; mild fever (after large I.M. dosage); hyperpyrexia; increased appetite and weight; a systemic lupus erythematosus-like syndrome; peripheral edema. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 10 mg., 25 mg., 50 mg., 100 mg. and 200 mg., in bottles of 100; Spansule® capsules, 30 mg., 75 mg., 150 mg., 200 mg. and 300 mg., in bottles of 50; Injection, 25 mg./ml.; Syrup, 10 mg./5 ml.; Suppositories, 25 mg. and 100 mg.; Concentrate, 30 mg./ml. and 100 mg./ml.

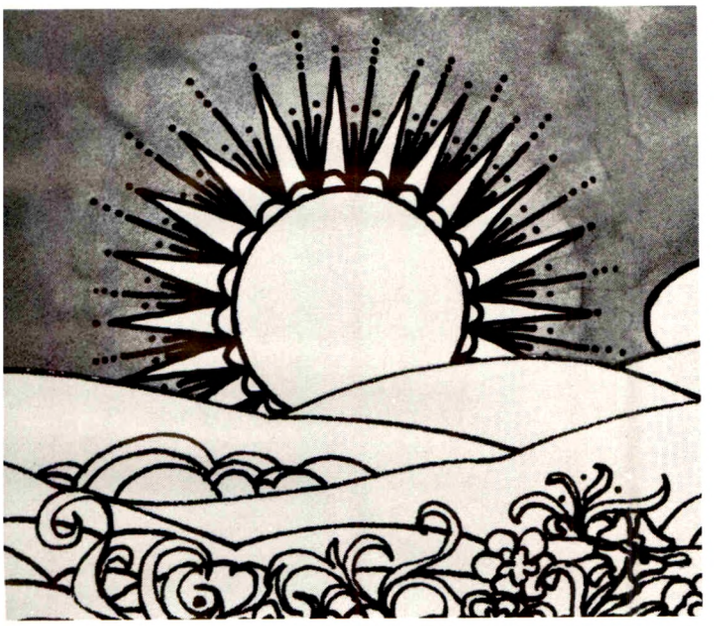
THORAZINE®

brand of

C [illegible] K [illegible] M [illegible] ZI E



Tablets:
50 mg. of the HCl

The new-day constant for drug-induced parkinsonism:

ARTANE®
TRIHEXYPHENIDYL HCl

Non-cumulative action makes each day of therapy a new day

That's why ARTANE is ideally suited for the patient on long-term phenothiazine therapy. In economical tablets or SEQUELS Sustained Release Capsules*, it offers you *more* than the rapid reversal of extrapyramidal symptoms.

Usually there is no drug buildup to cause undue toxicity in prolonged therapy. Minimal atropine-like side effects. Accurate dosage titration in adjunctive use. And, to minimize missed doses and anxiety in outpatient therapy— one-dose *all-day* control or prevention with SEQUELS.*

For hospitalized or ambulatory patients, ARTANE has the "constant" they need. Effective *non-cumulative* action.

Tablets—2 mg, 5 mg; Elixir†—2 mg/5 cc or SEQUELS® Sustained Release Capsules—5 mg.

Tablets and Elixir Indications: FDA has evaluated this drug as Effective as an adjunct in the therapy of the indications listed below under SEQUELS.

***INDICATIONS FOR ARTANE SEQUELS:**
Based on a review of this drug in sustained release form by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows: Probably effective as an adjunct in the therapy of all forms of parkinsonism (postencephalitic, arteriosclerotic, and idiopathic) and for use in the prevention or control of extrapyramidal disorders due to central nervous system drugs such as reserpine and phenothiazines.

WARNING:
Patients to be treated should have a gonioscope evaluation and close monitoring of intraocular pressures at regular periodic intervals.

Precautions: Patients with cardiac, liver or kidney disorders or with hypertension should be maintained under close observation. In long-term therapy, take care to avoid allergic and other untoward reactions. Use with caution in patients with glaucoma, obstructive disease of the gastrointestinal or genitourinary tracts and in elderly males with possible prostatic hypertrophy. Geriatric patients require strict dosage regulation. Incipient glaucoma may be precipitated.

Adverse Reactions: Such effects as dryness of mouth, blurring of vision, dizziness, nausea or nervousness will be experienced by 30 to 50 per cent of patients. (These tend to lessen and can often be controlled by adjusting dosage.) Isolated instances of suppurative parotitis, skin rashes, dilation of the colon, paralytic ileus, delusions, hallucinations and paranoia (1 doubtful case) have been reported. Patients with arteriosclerosis or with a history of idiosyncrasy to drugs may exhibit mental confusion, agitation, disturbed behavior, or nausea and vomiting. If a severe reaction occurs, discontinue drug for a few days, then resume at lower dosage. Psychiatric disturbances can result from overdosage to sustain euphoria. Side effects of any atropine-like drugs include constipation, drowsiness, urinary hesitancy or retention, tachycardia, dilation of the pupil, increased intraocular tension, weakness, vomiting and headache.

†Lime-mint flavored, with 0.08% methylparaben, 0.02% propylparaben, and 5% alcohol as preservatives.

*This drug in sustained release form has been evaluated as probably effective. See Brief Summary.

See next page for brief summary.

EMOTIONAL WITHDRAWAL
CONCEPTUAL DISORGANIZATION / ANXIETY
TENSION / HALLUCINATORY BEHAVIOR
SUSPICIOUSNESS / BLUNTED AFFECT

One or more of these symptoms in a schizophrenic is an indication for

Contraindications: Severe central nervous system depression, comatose states, hypersensitivity.

Warnings: Increase dosage gradually to patients participating in activities requiring complete mental alertness (e.g., driving). The safety of this drug in pregnancy has not been established; hence, it should be given only when the anticipated benefits to be derived from treatment exceed the possible risks to mother and fetus. Use in children under 12 is not recommended. Phenothiazines are capable of potentiating central nervous system depressants as well as atropine and phosphorus insecticides.

Precautions: Ocular changes (seen with other phenothiazines) have not been seen with Serentil (mesoridazine). Because of possible hypotensive reactions, caution in parenteral use is required. Reserve parenteral administration for bedfast patients or for acute ambulatory cases, and keep patient lying down for at least ½ hour after injection. Leukopenia and/or agranulocytosis have been attributed to phenothiazine therapy. Blood dyscrasia (seen with other phenothiazines) has occurred in a single case of transient granulocytopenia.

Adverse Reactions: Serentil (mesoridazine) has demonstrated a remarkably low incidence of adverse reactions when compared with other phenothiazine compounds. *Central Nervous System:* Drowsiness, Parkinson's syndrome, dizziness, weakness, tremor, restlessness, ataxia, dystonia, rigidity, slurring, akathisia, motoric reactions (opisthotonos). *Autonomic Nervous System:* Dry mouth, nausea and vomiting, fainting, stuffy nose, photophobia, constipation and blurred vision. *Endocrine System:* Inhibition of ejaculation and lactation have been noted rarely. *Skin:* Itching, rash, hypertrophic papillae of the tongue and angioneurotic edema. *Cardiovascular System:* Hypotension, tachycardia, EKG changes.

The following reactions have occurred with phenothiazines and should be considered: *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Serentil (mesoridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. There is no evidence that these changes are precursors of any significant disturbance of cardiac rhythm. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonos, oculogyric crises, tremor, muscular rigidity, and akinesia, occasionally persisting for several months or years especially in elderly patients with brain damage. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, weight gain, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia, behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea.

Dosage and Administration: ORAL: Should be adjusted to needs of the individual. Lowest effective dosage should always be used. When maximum response is achieved, dosage may be reduced gradually to maintenance level. *Schizophrenia:* For most patients, regardless of severity, starting dose of 50 mg. t.i.d. recommended. Usual optimum total daily dose range 100-400 mg. *Behavioral Problems in Mental Deficiency and Chronic Brain Syndrome:* For most patients starting dose of 25 mg. t.i.d. recommended. Usual optimum total daily dose range 75-300 mg. *Alcoholism:* For most patients usual starting dose is 25 mg. b.i.d. Usual optimum total daily dose range 50-200 mg. *Psychoneurotic Manifestations:* For most patients usual starting dose is 10 mg. t.i.d. Usual optimum total daily dose range 30-150 mg. INJECTABLE FORM: For situations in which an intramuscular form of medication is indicated. For most patients a starting dose of 25 mg. is recommended, to be repeated in 30-60 minutes if necessary. Usual optimum total daily dose range 25-200 mg.

Before prescribing, consult package circular.

Sandoz Pharmaceuticals/East Hanover, N.J. 07936

SANDOZ

SER 72-239

Withdrawn and uncommunicative?...Or responsive?

While psychotic symptoms remain acute, the barrier between you and the withdrawn, uncommunicative patient may be insurmountable. Prompt intervention with HALDOL (haloperidol) often makes it possible for you to reach... relate...rehabilitate.

And rapport with such patients is further enhanced because HALDOL usually leaves patients alert and relatively non-sedated.

responsiveness often begins with

HALDOL® (haloperidol)

For information relating to Indications, Contraindications, Warnings, Precautions and Adverse Reactions, please turn page.

© McNeil Laboratories, Inc. 1973

Haldol®
(HALOPERIDOL)

a first choice for prompt rapport

A Dosage Form for Every Need:

4 tablet strengths for convenience in individualizing dosage: ½ mg., 1 mg., 2 mg. and 5 mg.

An undetectable, tasteless Liquid Concentrate for the patient unable or unwilling to swallow tablets: 2 mg. per cc.

A rapid-acting Injection for psychiatric emergencies: 5 mg. per cc., with 0.5 mg. methylparaben and 0.05 mg. propylparaben per cc., and lactic acid for pH adjustment to 3.4±0.2.

Summary of Directions for Use

Indications: For the treatment of such symptoms as moderate to severe agitation, anxiety and tension, assaultiveness, delusions, hallucinations, hostility, and hyperactivity when they are manifestations of psychosis including schizophrenia, the manic type of manic depressive illness, or psychotic reactions associated with organic brain syndromes or mental retardation. For the control of tics and vocal utterances of Gilles de la Tourette's Syndrome.

Contraindications: HALDOL (haloperidol) is contraindicated in patients who are severely depressed, comatose, have CNS depression due to alcohol or other centrally-acting depressants, have Parkinson's disease or are hypersensitive to this drug.

Warnings: ***Usage in Pregnancy***—Safe use of HALDOL (haloperidol) in pregnancy and lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the possible benefits of the drug be weighed against the potential hazards. A case of phocomelia in an infant whose mother received haloperidol along with a number of other medications during the first trimester of pregnancy has been reported (a causal relationship was not established in this case). Animals receiving 2 to 20 times the maximum human dose of HALDOL orally and/or parenterally showed increased incidence of resorption, reduced fertility, delayed delivery, dose-related pup mortality (presumably due to lack of maternal care reflecting CNS depression).

Usage in Children—Safety and effectiveness in children have not been established; therefore, this drug is not recommended for use in the pediatric age group.

General—Cases of bronchopneumonia, some fatal, have followed the use of major tranquilizers, including haloperidol. It has been postulated that lethargy and decreased sensation of thirst may lead to dehydration, hemoconcentration and reduced pulmonary ventilation. If these signs and symptoms appear, especially in the elderly, the physician should institute remedial therapy promptly. Although not reported with HALDOL (haloperidol), decreased serum cholesterol and/or cutaneous and ocular changes have been reported in patients receiving chemically-related drugs. HALDOL may impair the mental and/or physical abilities required for the performance of hazardous tasks such as operating machinery or driving a motor vehicle. The ambulatory patient should be warned accordingly. The use of alcohol should be avoided due to possible additive effects and hypotension.

Precautions: HALDOL (haloperidol) should be administered cautiously to patients: (1)—with severe cardiovascular disorders, because of the possibility of transient hypotension and/or precipitation of anginal pain. Should hypotension occur and a vasopressor be required, *epinephrine should not be used* since HALDOL may block its vasopressor activity and paradoxical further lowering of blood pressure may occur. (2)—receiving anticonvulsant medication, because HALDOL may lower the convulsive threshold, although it will *not* increase the effects of anticonvulsant medication. Adequate anticonvulsant therapy should be maintained concomitantly. (3)—with known allergies, or with a history of allergic reactions to drugs. (4)—receiving anticoagulants, since an isolated instance of interference occurred with the effects of one anticoagulant (phenindione).

If concomitant anti-Parkinson medication is required, it may have to be continued after haloperidol is discontinued because of the difference in excretion rates. If both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including anti-Parkinson agents, are administered concomitantly with HALDOL. When HALDOL is used to control mania in cyclic disorders there may be a rapid mood swing to depression.

Adverse Reactions: ***CNS Effects:*** *Extrapyramidal Reactions*—Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which usually were mild to moderately severe and reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally extrapyramidal symptoms are dose related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Administration of anti-Parkinson drugs may be required for control of such reactions. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases. *Other CNS Effects*—Insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, grand mal seizures, and exacerbation of psychotic symptoms including hallucinations. ***Cardiovascular Effects:*** Tachycardia and hypotension. ***Hematologic Effects:*** Reports have appeared of mild and usually transient leukopenia and leukocytosis, minimal decreases in red blood cell counts, anemia, or a tendency toward lymphomonocytosis. Agranulocytosis has rarely been reported and then only in association with other medication. ***Liver Effects:*** Impaired liver function and/or jaundice have been reported, although a causal relationship has not been established. ***Dermatologic Reactions:*** Maculopapular and acneiform skin reactions and isolated cases of photosensitivity and loss of hair. ***Endocrine Disorders:*** Lactation, breast engorgement, mastalgia, menstrual irregularities, gynecomastia, impotence, increased libido, hyperglycemia and hypoglycemia. ***Gastrointestinal Effects:*** Anorexia, constipation, diarrhea, hypersalivation, dyspepsia, nausea and vomiting. ***Autonomic Reactions:*** Dry mouth, blurred vision, urinary retention and diaphoresis. ***Respiratory Effects:*** Laryngospasm, bronchospasm and increased depth of respiration.

Complete dosage information available in insert which accompanies each package (or on request).

The use of the injectable form is intended for the acutely agitated psychotic patient with moderately severe to very severe symptoms.

IMPORTANT: Full directions for use should be read before HALDOL (haloperidol) is administered or prescribed. 11/72

Today, she managed a smile

(Not long ago, she couldn't stop sobbing)

Before he sees that first positive response—however hesitant and tentative—the physician may have to bring into play many different aspects of therapy. Establishing a therapeutic relationship may be the first difficulty as well as the first necessity. Psychotherapy, family and community support, occupational and social counseling, and drug therapy may all have to be enlisted.

The characteristically rapid energizing action of VIVACTIL may help establish early therapeutic rapport by lessening the patient's lethargy—often during the first week of medication. VIVACTIL helps elevate mood, usually within the third or fourth week of treatment.

Characteristically, the drug has no sedating or tranquilizing properties. (Symptoms such as anxiety or agitation may be aggravated.)

Dosage of VIVACTIL must be individualized, and patients should be under close medical supervision. For many adult patients with clinically significant depression, 10 mg t.i.d. may provide control of symptoms. Others may require as little as 15 mg or as much as 60 mg a day. In elderly patients and adolescents, lower dosages are recommended.

In depression,

TABLETS, 5 mg and 10 mg

Vivactil®

(Protriptyline HCl | MSD) helps establish early therapeutic rapport

ontraindications: Known hypersensitivity; acute recovery phase following myocardial farction. Not recommended for use in children. Should not be given concomitantly with n MAOI; hyperpyretic crises, severe convulsions, and deaths have occurred in patients ceiving tricyclic antidepressant and MAOI drugs simultaneously. When it is desired to ubstitute protriptyline HCl for an MAOI, a minimum of 14 days should be allowed to elapse fter the latter is discontinued. Protriptyline HCl should then be initiated cautiously with radual increase in dosage until optimum response is achieved.

arnings: May block the antihypertensive effect of guanethidine or similarly acting compounds. May impair mental and/or physical abilities required for the performance of azardous tasks, such as operating machinery or driving a motor vehicle. Should be used ith caution in patients with a history of seizures and, because of its autonomic activity, n patients with a tendency to urinary retention or increased intraocular tension.

achycardia and postural hypotension may occur more frequently than with other antiepressant drugs. Should be used with caution in elderly patients and patients with ardiovascular disorders; such patients should be observed closely because of the tency of the drug to produce tachycardia, hypotension, arrhythmias, and prolongation f the conduction time. Myocardial infarction and stroke have occurred with drugs of this lass. On rare occasions, hyperthyroid patients or those receiving thyroid medication ay develop arrhythmias when this drug is given.

sage in Children: Not recommended for use in children because safety and effectiveness n the pediatric age group have not been established.

sage in Pregnancy: Safe use in pregnancy and lactation has not been established; therefore, use in pregnant women, nursing mothers, or women who may become pregnant equires that possible benefits be weighed against possible hazards to mother and child.

recautions: When protriptyline HCl is used to treat the depressive component of schizophrenia, psychotic symptoms may be aggravated; likewise, in manic-depressive psychosis, epressed patients may experience a shift toward the manic phase; paranoid delusions, ith or without associated hostility, may be exaggerated. In any of these circumstances, may be advisable to reduce the dose of protriptyline HCl or to use a major tranquilizing rug, such as perphenazine, concurrently. Symptoms, such as anxiety or agitation, may e aggravated in overactive or agitated patients.

hen given with anticholinergic agents or sympathomimetic drugs, close supervision nd careful adjustment of dosages are required. In healthy test subjects, maximum herapeutic doses significantly potentiated the peripheral circulatory effects of intravenous norepinephrine and epinephrine (manifested by undue increase in systolic and iastolic blood pressure and decrease in pulse rate). May enhance the response to alcohol nd the effects of barbiturates and other CNS depressants. The possibility of suicide in epressed patients remains during treatment and until significant remission occurs; this ype of patient should not have easy access to large quantities of the drug. Concurrent dministration with electroshock therapy may increase the hazards of therapy; such reatment should be limited to patients for whom it is essential. Discontinue the drug everal days before elective surgery, if possible.

dverse Reactions: *Note:* Included in this listing are a few adverse reactions which have ot been reported with this specific drug. However, the pharmacologic similarities among he tricyclic antidepressant drugs require that each of the reactions be considered when rotriptyline HCl is administered. Protriptyline HCl is more likely to aggravate agitation nd anxiety and produce cardiovascular reactions such as tachycardia and hypotension.

ardiovascular: hypotension, hypertension, tachycardia, palpitation, arrhythmias.

NS and Neuromuscular: confusional states (especially in the elderly); disorientation; delusions; hallucinations; anxiety; agitation; restlessness; insomnia; numbness, tingling, nd paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremor; seizures.

Anticholinergic: dry mouth and, rarely, associated sublingual adenitis; blurred vision; disturbance of accommodation; mydriasis; constipation; urinary retention; dilatation of the urinary tract.

Other: skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight), edema (general, or of face and tongue), nausea, vomiting, epigastric distress, anorexia, peculiar taste, stomatitis, parotid swelling, impotence, jaundice (simulating obstructive), drowsiness, dizziness, weakness, fatigue, headache, perspiration, weight gain or loss, urinary frequency.

Withdrawal Symptoms: In an occasional patient, abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

The following adverse reactions have been reported less frequently with the class of antidepressant agent to which protriptyline HCl belongs: myocardial infarction, heart block, stroke, panic, nightmares, alteration in EEG patterns, hypomania, exacerbation of psychosis, extrapyramidal symptoms, tinnitus, paralytic ileus, delayed micturition, drug fever, bone-marrow depression, agranulocytosis, eosinophilia, purpura, thrombocytopenia, diarrhea, abdominal cramps, black tongue, testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, altered liver function, flushing, nocturia, alopecia.

Supplied: Tablets, containing 5 mg and 10 mg protriptyline HCl each, in single-unit packages of 100 and bottles of 100 and 1000.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486

addendum

MSD
MERCK
SHARP
DOHME

MSD 26 5 mg (orange)

MSD 47 10 mg (yellow)

The usual regimen for adults is 15 to 40 mg a day divided into three or four doses. Dosage may be increased to 60 mg a day if necessary.

In elderly and adolescent patients, lower dosages are recommended; initially, a regimen of 5 mg t.i.d. is suggested with adjustment as necessary to the required amount. In elderly patients, the cardiovascular system must be monitored closely when the daily dose exceeds 20 mg.

Because VIVACTIL (Protriptyline HCl, MSD) characteristically is a nonsedating tricyclic antidepressant, activating and energizing in effect, the last dose of the day should be given no later than mid-afternoon to avoid insomnia. Required increases should be added to the morning dose.

When necessary to increase dosage, it should be done gradually. After satisfactory improvement has been achieved, dosage should be reduced to the smallest amount that will maintain relief of symptoms. Maintenance therapy should be continued for at least three months after satisfactory improvement occurs.

(*Usage in Children:* In view of the lack of experience in children, this drug is not recommended for patients under 12 years of age.)

A good morning after a sleep-through night

A good morning should be just that—and not a morning of grogginess and diminished alertness. A good reason why you should consider Quāālude® for your insomniac patients and those whose sleep patterns have been altered by disease or surgery.

Quāālude-300 is usually effective *in inducing 6 to 8 hours of restful sleep in the sleepless, generally within 10 to 30 minutes.*

And, *usually the patient awakens easily, without a "hangover" due to residual hypnotic effect.*

Non-barbiturate Quāālude-300 is chemically unrelated to other sedative-hypnotics. Its therapeutic value has been established in controlled clinical studies and by wide physician usage of methaqualone throughout the world.

Side effects reported have been mild, transient, and have often proved to be statistically insignificant when compared to placebo effects. Caution must be exercised in administering methaqualone to individuals known to be addiction-prone or those whose history suggests they may increase the dosage on their own initiative. (See "Warnings" and "Adverse Reactions" sections in brief summary below.)

The next time you're facing a patient with insomnia who needs your help, prescribe Quāālude-300. He'll usually sleep better—and wake up better, too.

a non-barbiturate sedative-hypnotic

Quāālude®-300
(methaqualone) **300 mg. tablets**

Brief Summary of Prescribing Information

Indications: Sleep. Daytime sedation.

Usual Adult Dose: *For sleep,* 150-300 mg. at bedtime. For patients previously on other hypnotics, 300 mg. for five to seven nights. *For sedation,* 75 mg. t.i.d. or q.i.d. Not recommended in children. Dosage should be individualized for aged, debilitated or highly agitated patients.

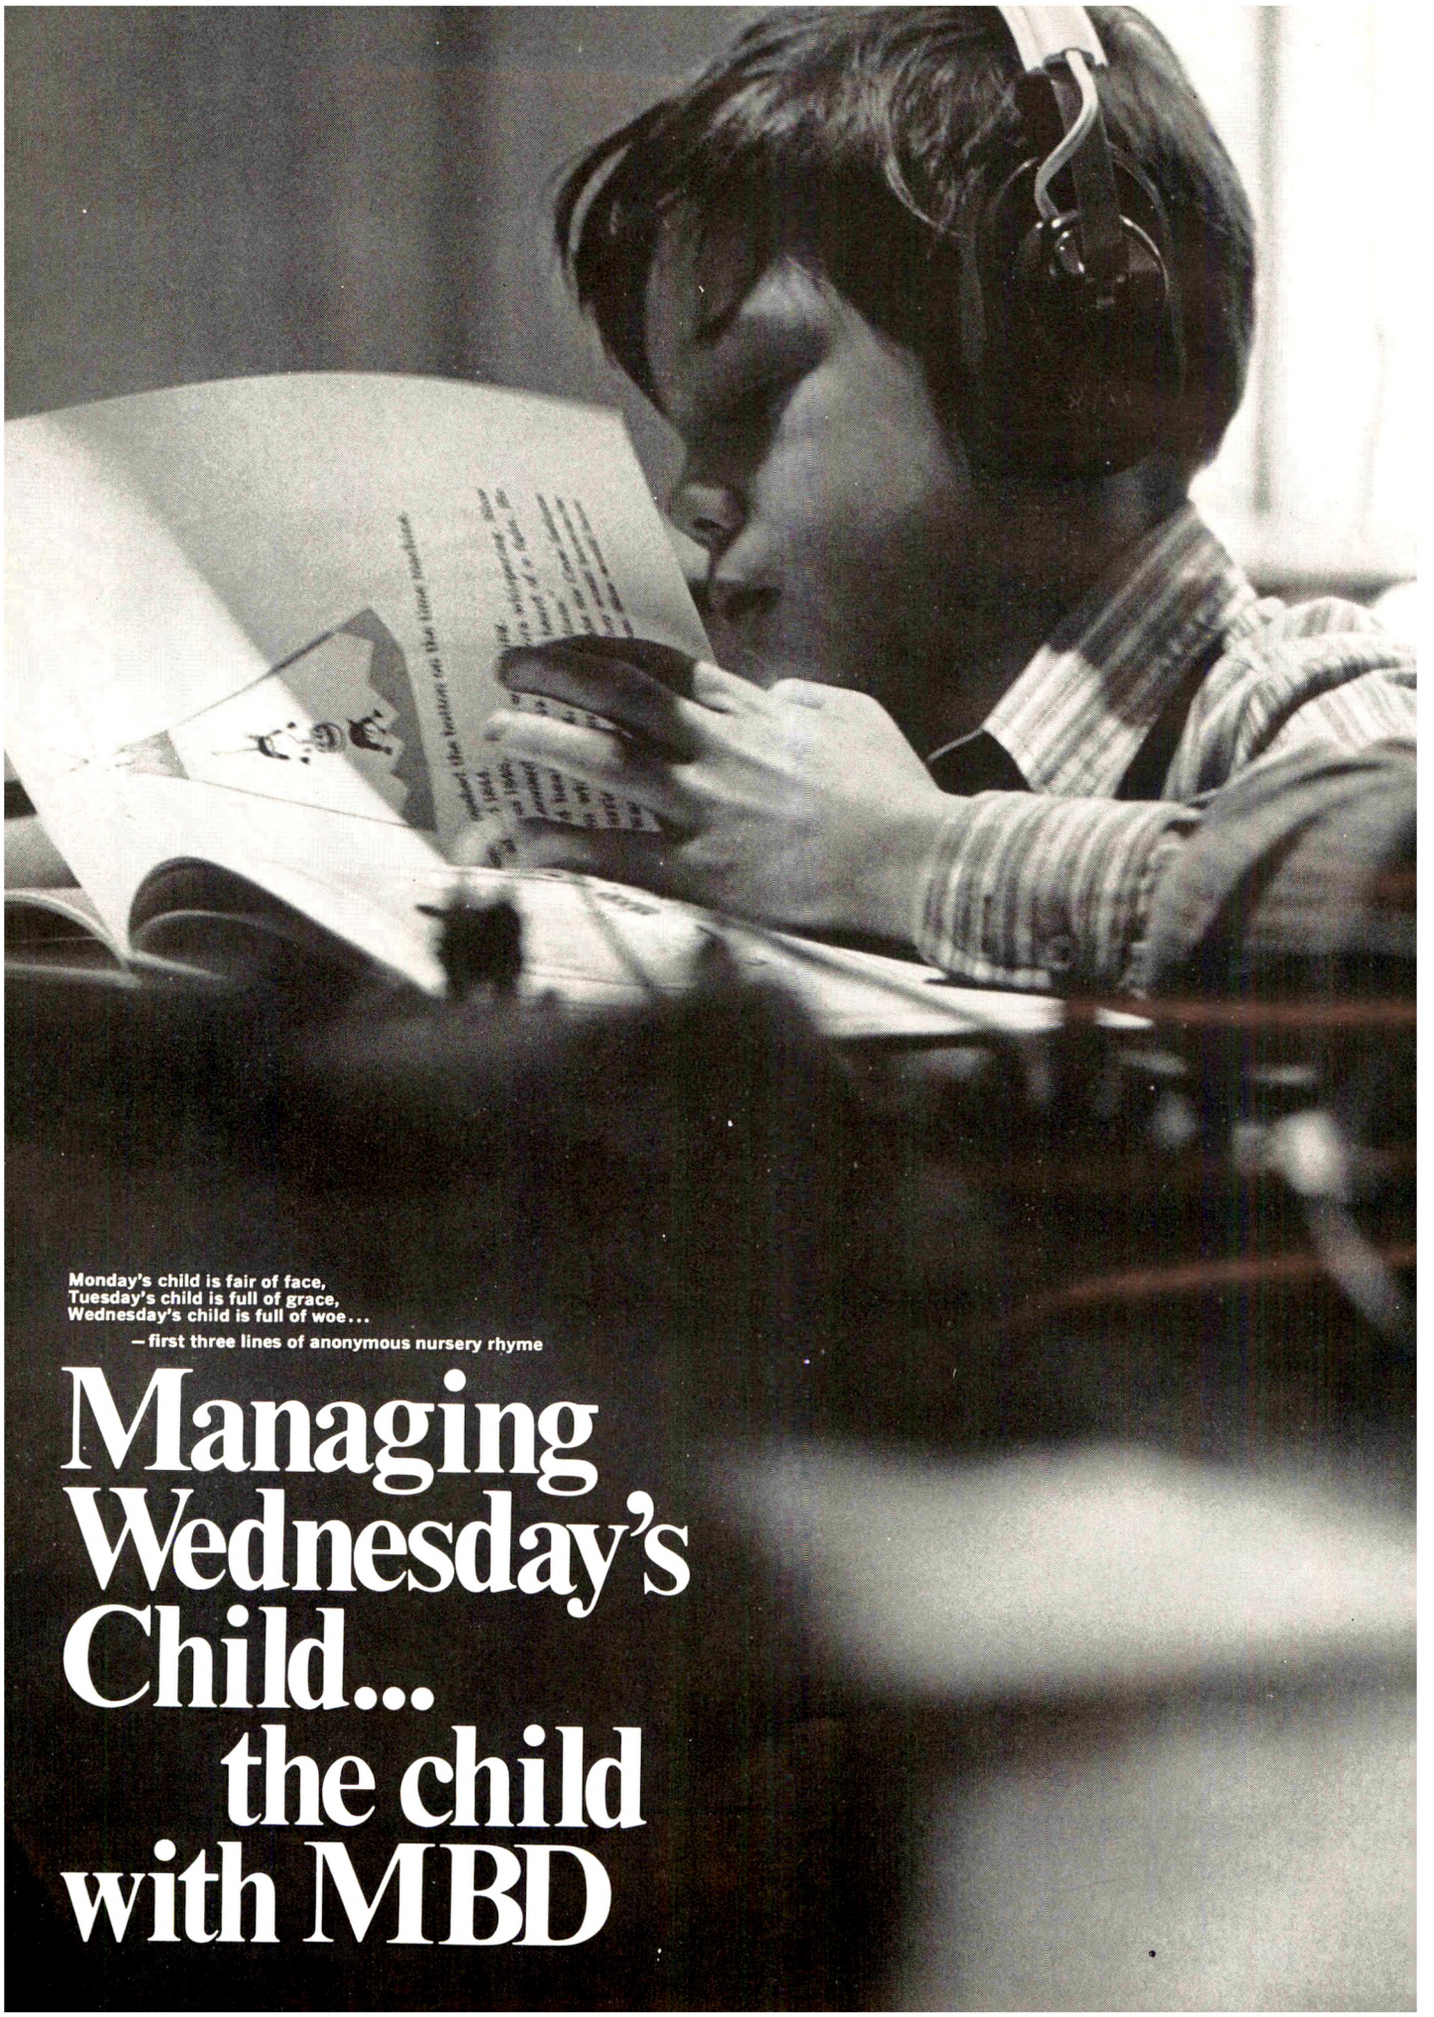
NEW FORMULATION: PROVIDES INCREASED ABSORPTION; THERAPEUTIC RESPONSE MAY BE MORE PROMPT AND PRONOUNCED. WARN PATIENTS, USING DRUG FOR SEDATION, AGAINST OPERATING CAR OR DANGEROUS MACHINERY.

Overdosage: Acute overdosage may result in delirium and coma, with restlessness and hypertonia, progressing to convulsions. Evacuate gastric contents, maintain adequate ventilation and support blood pressure, if necessary. Dialysis may be helpful. Analeptics are contraindicated. Succinylcholine accompanied by assisted respiration has been proposed for prolonged convulsions. Overdoses of methaqualone appear to be less often associated with cardiac or respiratory depression than are overdoses of oral barbiturates, but shock and respiratory arrest may occasionally occur.

Contraindications: Contraindicated in women who are or may become pregnant; or patients with known hypersensitivity.

Warnings: Take hypnotic dose only at bedtime. Not recommended in children. Warn patient on Quāālude against driving a car or operating dangerous machinery. Care needed when administered with other sedative, analgesic or psychotropic drugs or alcohol because of possible additive effects. Pending longer clinical experience, Quāālude (methaqualone) should not be used continuously for periods exceeding three months. *Psychological dependence* occasionally occurs. *Physical dependence* rarely reported. However, caution needed with addiction-prone patients.

Precautions: Use with caution and prescribe small quantities in patients with anxiety states where impending depression or suicidal tendencies exist. Give in reduced doses, if at all, in patients with impaired hepatic function.



Adverse Reactions: *Neuropsychiatric:* headache, hangover, fatigue, dizziness, torpor, transient paresthesia of the extremities. An occasional patient has experienced restlessness or anxiety. *Hematologic:* aplastic anemia possibly related to methaqualone has been very rarely reported. *Gastrointestinal:* dry mouth, anorexia, nausea, emesis, epigastric discomfort, diarrhea. *Dermatologic:* diaphoresis, bromhidrosis, exanthema. Urticaria has been particularly well documented.

Supplied: Quāālude-150 (150 mg. white, scored tablets). Quāālude-300 (300 mg. white, scored tablets).

Consult complete literature before prescribing.

ROHRER

Monday's child is fair of face,
Tuesday's child is full of grace,
Wednesday's child is full of woe...

—first three lines of anonymous nursery rhyme

Managing Wednesday's Child... the child with MBD

Vednesday's child is full of woe"
It need not be this way for the MBD child.
He can learn and adjust if given helping hand.

Without help, the MBD child may be a ow reader, can find writing difficult, and rithmetic hard to grasp. He may be excitable, nd his actions can be disruptive. The result can eriously hamper his educational and social evelopment.

But, properly diagnosed and treated, MBD - Minimal Brain Dysfunction – can be brought nder control so that the afflicted child can evelop normally.

And Ritalin can play an important part in ıe total rehabilitation program f the MBD child, which includes emedial measures at home and t school. It's currently the rug of choice in many MBD tuations.[1]

Ritalin is well tolerated. It an help control the excessive ıotor activity of the MBD child nd ameliorate behavioral and earning problems.

Of course, Ritalin is not ıdicated for childhood personality and behavioral disorders not associated with MBD.

ABLETS

IDICATION

inimal Brain Dysfunction in Children—as adjunctive therapy to her remedial measures (psychological, educational, social)

ecial Diagnostic Considerations

ecific etiology of Minimal Brain Dysfunction (MBD) is unknown, ıd there is no single diagnostic test. Adequate diagnosis requires e use not only of medical but of special psychological, educaonal, and social resources.

ıe characteristic signs most often observed are chronic history of ıort attention span, distractibility, emotional lability, impulsivity, ıd moderate to severe hyperactivity; specific learning disabilities; erceptual motor impairment; minor neurological signs and abnoral EEG. The diagnosis of MBD must be based upon a complete story and evaluation of the child and not solely on the presence of ıe or more of these signs.

rug treatment is not indicated for all children with MBD. Appropiate educational placement is essential and psychological or social tervention may be necessary. When remedial measures alone are sufficient, the decision to prescribe stimulant medication will epend upon the physician's assessment of the chronicity and severity the child's symptoms.

ONTRAINDICATIONS

arked anxiety, tension, and agitation, since Ritalin may aggravate ese symptoms. Also contraindicated in patients known to be hypernsitive to the drug and in patients with glaucoma.

ARNINGS

talin is not recommended for children under six years, since ıfety and efficacy in this age group have not been established. nce sufficient data on safety and efficacy of long-term use of talin in children with minimal brain dysfunction are not yet availble, those requiring long-term therapy should be carefully monitored. talin should not be used for severe depression of either exogenous endogenous origin or for the prevention of normal fatigue states. italin may lower the convulsive threshold in patients with or without prior seizures; with or without prior EEG abnormalities, even in absence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. If seizures occur, Ritalin should be discontinued.

Use cautiously in patients with hypertension.

Drug Interactions

Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors. Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy

Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence

Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.

Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS

Patients with an element of agitation may react adversely; discontinue therapy if necessary. Periodic CBC and platelet counts are advised during prolonged therapy.

ADVERSE REACTIONS

Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include: hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, and erythema multiforme with histopathological findings of necrotizing vasculitis); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmias; abdominal pain; weight loss during prolonged therapy. In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently. Toxic psychosis has been reported.

DOSAGE AND ADMINISTRATION

Children with Minimal Brain Dysfunction (6 years and over)

Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.

If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.

Ritalin should be periodically discontinued to assess the child's condition. Improvement may be sustained when the drug is either temporarily or permanently discontinued.

Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED

Tablets, 20 mg (peach, scored); bottles of 100 and 1000.
Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Strip Dispensers of 100.
Tablets, 5 mg (pale yellow); bottles of 100, 500, and 1000.

only when medication is indicated

C I B A

A57

The psychoneurotic patient's prognosis may be good...

As a group, psychoneurotic patients tend to respond positively to psychotherapy. Follow-up studies indicate that up to two-thirds of treated patients may show significant and often sustained improvement.

In individual cases, the prognosis appears particularly favorable for the psychoneurotic who has had a good premorbid personality structure and a record of reasonably good interpersonal competence. As might be expected, patients judged to be "attractive" candidates for therapy often tend to derive greater benefits from therapeutic intervention than those considered "unattractive."

The global assessment of "attractiveness" is influenced by such factors as youthfulness, intelligence, ability to relate and good occupational history.

But excessive anxiety can block recovery...

Anxiety is the hallmark of psychoneurotic states. In excess it may not alter the patient's "prognostic rating," but it can slow therapeutic progress—sometimes to a marked extent. At the outset of therapy, for instance, severe or persistent anxiety can be particularly

obstructive, sometimes hampering for long periods the patient's ability to participate in a productive psychotherapeutic relationship. At later stages, intense anxiety may impair the patient's receptivity to further probing and block his attempts to retrieve and express pertinent material.

When the patient's disabling anxiety continues to impede therapeutic progress, management of his condition may often be significantly facilitated by adjunctive Librium (chlordiazepoxide HCl).

Librium generally relieves excessive anxiety without unduly impairing mental acuity or ability to perform. As with all CNS-acting drugs, however, patients should be cautioned against hazardous occupations requiring complete mental alertness. (See Warnings section in summary of prescribing information.) When the patient's anxiety has been reduced to appropriate levels, Librium should, of course, be discontinued.

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.
Contraindications: Patients with known hypersensitivity to the drug.
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported. Use of any drug in pregnancy, lactation, or in women of childbearing age requires that its potential benefits be weighed against its possible hazards.
Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.
Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido —all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.
Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.

To relieve obstructive anxiety consider

HELP KEEP HIM OUT OF THE BAR

Bars may draw him like a magnet. Not for social reasons as much as antisocial ones. His drinking hurts himself and others close to him. He's an alcoholic, a public health problem, and a menace behind the wheel of a car. He's ill and needs your help and treatment.

For more than 20 years now, ANTABUSE has proved its effectiveness as a medical adjunct in the management of alcoholics who want to recover. ANTABUSE offers strong deterrent action. It can help keep the alcoholic sober so that he can participate in a total treatment program utilizing many supportive measures.

Once the alcoholic accepts ANTABUSE therapy, he has made his decision to stop drinking. By taking his tablet each day, he dai strengthens his resolve. The patient must be given a clear and detailed description of the effects of ingesting alcohol after he has taker ANTABUSE even up to 14 days after the last dose. ANTABUSE is nonhabituating; there is no danger of cross-addiction.

ANTABUSE

Brand of DISULFIRAM

a strong deterrent for the alcoholic who doesn't want to drink

See opposite page for brief summary of prescribing information

ANTABUSE® (DISULFIRAM)

a strong deterrent for the alcoholic who doesn't want to drink

BRIEF SUMMARY *(For full prescribing information, see package circular.)*

ANTABUSE® Brand of disulfiram
In Alcoholism

INDICATION: ANTABUSE is an aid in the management of selected chronic alcoholic patients who want to remain in a state of enforced sobriety so that supportive and psychotherapeutic treatment may be applied to best advantage. (Used alone, without proper motivation and without supportive therapy, ANTABUSE is not a cure for alcoholism, and it is unlikely that it will have more than a brief effect on the drinking pattern of the chronic alcoholic.)

CONTRAINDICATIONS: Patients who are receiving or have recently received metronidazole, paraldehyde, alcohol, or alcohol-containing preparations, *e.g.* cough syrups, tonics, and the like, should not be given ANTABUSE.

ANTABUSE is contraindicated in the presence of severe myocardial disease or coronary occlusion, psychoses, or hypersensitivity.

WARNINGS

ANTABUSE should never be administered to a patient when he is in a state of alcohol intoxication or without his full knowledge.

The physician should instruct relatives accordingly.

The patient must be fully informed of the ANTABUSE-alcohol reaction. He must be strongly cautioned against surreptitious drinking while taking the drug, and he must be fully aware of possible consequences. He should be warned to avoid alcohol in disguised form, *i.e.* in sauces, vinegars, cough mixtures, and even aftershave lotions and back rubs. He should also be warned that reactions may occur with alcohol up to 14 days after ingesting ANTABUSE.

THE ANTABUSE-ALCOHOL REACTION: ANTABUSE plus alcohol, even small amounts, produces flushing, throbbing in head and neck, throbbing headache, respiratory difficulty, nausea, copious vomiting, sweating, thirst, chest pain, palpitation, dyspnea, hyperventilation, tachycardia, hypotension, syncope, marked uneasiness, weakness, vertigo, blurred vision, and confusion. In severe reactions there may be respiratory depression, cardiovascular collapse, arrhythmias, myocardial infarction, acute congestive heart failure, unconsciousness, convulsions, and death.

The intensity of the reaction varies with each individual, but is generally proportional to the amounts of ANTABUSE (disulfiram) and alcohol ingested. Mild reactions may occur in the sensitive individual when the blood alcohol concentration is increased to as little as 5 to 10 mg. per 100 cc. Symptoms are fully developed at 50 mg. per 100 cc., and unconsciousness usually results when the blood alcohol level reaches 125 to 150 mg.

The duration of the reaction varies from 30 to 60 minutes to several hours in the more severe cases, or as long as there is alcohol in the blood.

DRUG INTERACTIONS: Disulfiram appears to decrease the rate at which certain drugs are metabolized and so may increase the blood levels and the possibility of clinical toxicity of drugs given concomitantly.

Disulfiram should be used with caution in those patients receiving diphenylhydantoin and its congeners, since toxic levels of these antiepileptic agents have been reported during concomitant disulfiram therapy.

It may be necessary to adjust the dosage of oral anticoagulants upon beginning or stopping disulfiram, since disulfiram may prolong prothrombin time.

Patients taking isoniazid when disulfiram is given should be observed for the appearance of unsteady gait or marked changes in mental status and the disulfiram discontinued if such signs appear.

CONCOMITANT CONDITIONS: Because of the possibility of an accidental ANTABUSE-alcohol reaction, ANTABUSE (disulfiram) should be used with extreme caution in patients with any of the following conditions: diabetes mellitus, hypothyroidism, epilepsy, cerebral damage, chronic and acute nephritis, hepatic cirrhosis or insufficiency.

USAGE IN PREGNANCY: The safe use of this drug in pregnancy has not been established. Therefore, ANTABUSE should be used during pregnancy only when, in the judgment of the physician, the probable benefits outweigh the possible risks.

PRECAUTIONS: It is suggested that every patient under treatment carry an Identification Card, stating that he is receiving ANTABUSE and describing the symptoms most likely to occur as a result of the ANTABUSE-alcohol reaction. In addition, this card should indicate the physician or institution to be contacted in emergency. (Cards may be obtained from Ayerst Laboratories upon request.)

Alcoholism may accompany or be followed by dependence on narcotics or sedatives. Barbiturates have been administered concurrently with ANTABUSE (disulfiram) without untoward effects, but the possibility of initiating a new abuse should be considered.

Base line and follow-up transaminase tests (10-14 days) are suggested to detect any hepatic dysfunction that may result with ANTABUSE therapy. In addition, a complete blood count and a sequential multiple analysis-12 (SMA-12) test should be made every six months.

ADVERSE REACTIONS: (See Contraindications, Warnings, and Precautions.)

Occasional skin eruptions are, as a rule, readily controlled by concomitant administration of an antihistaminic drug.

In a small number of patients, a transient mild drowsiness, fatigability, impotence, headache, acneform eruptions, allergic dermatitis, or a metallic or garlic-like aftertaste may be experienced during the first two weeks of therapy. These complaints usually disappear spontaneously with the continuation of therapy or with reduced dosage.

Psychotic reactions have been noted, attributable in most cases to high dosage, combined toxicity (with metronidazole or isoniazid), or to the unmasking of underlying psychoses in patients stressed by the withdrawal of alcohol.

There have been reports of polyneuritis and peripheral neuritis, and rare instances of optic neuritis. One case of cholestatic hapatitis has been reported, but its relationship to ANTABUSE has not been unequivocally established.

DOSAGE AND ADMINISTRATION: ANTABUSE (disulfiram) should never be administered until the patient has abstained from alcohol for at least 12 hours.

INITIAL DOSAGE SCHEDULE: In the first phase of treatment, a maximum of 500 mg. daily is given in a single dose for one to two weeks. Although usually taken in the morning, ANTABUSE may be taken on retiring by patients who experience a sedative effect. Alternatively, to minimize, or eliminate, the sedative effect, dosage may be adjusted downward.

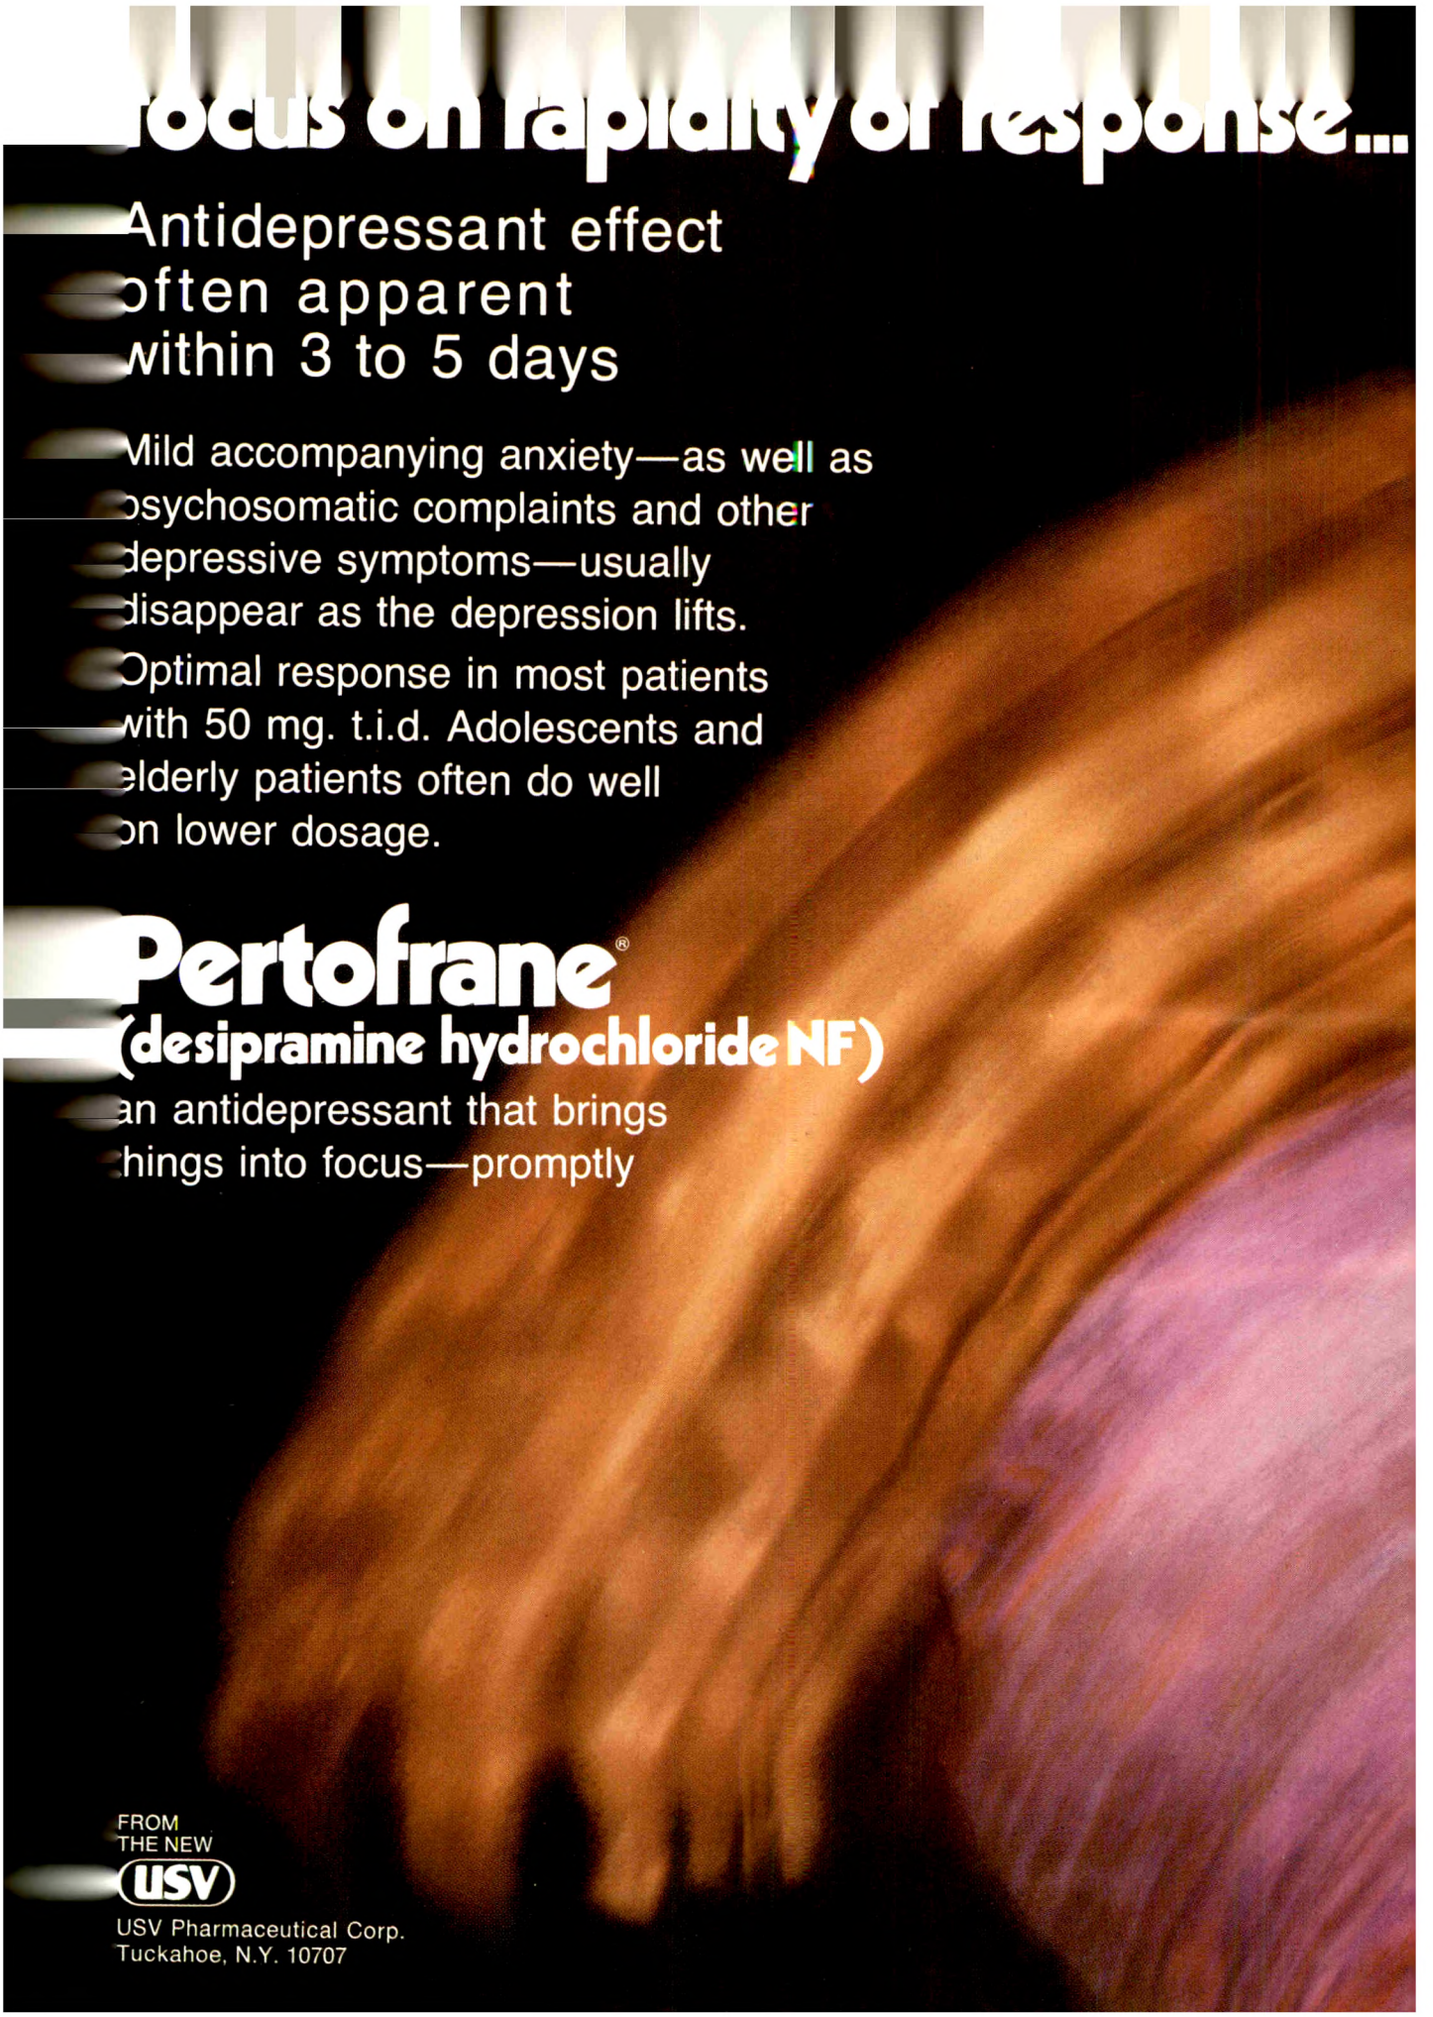
MAINTENANCE REGIMEN: The average maintenance dose is 250 mg. daily (range, 125 to 500 mg.); it should not exceed 500 mg. daily.

NOTE: Occasional patients, while seemingly on adequate maintenance doses of ANTABUSE, report that they are able to drink alcoholic beverages with impunity and without any symptomatology. All appearances to the contrary, such patients must be presumed to be disposing of their tablets in some manner without actually taking them. Until such patients have been observed reliably taking their daily ANTABUSE tablets (preferably crushed and well mixed with liquid), it cannot be concluded that ANTABUSE is ineffective.

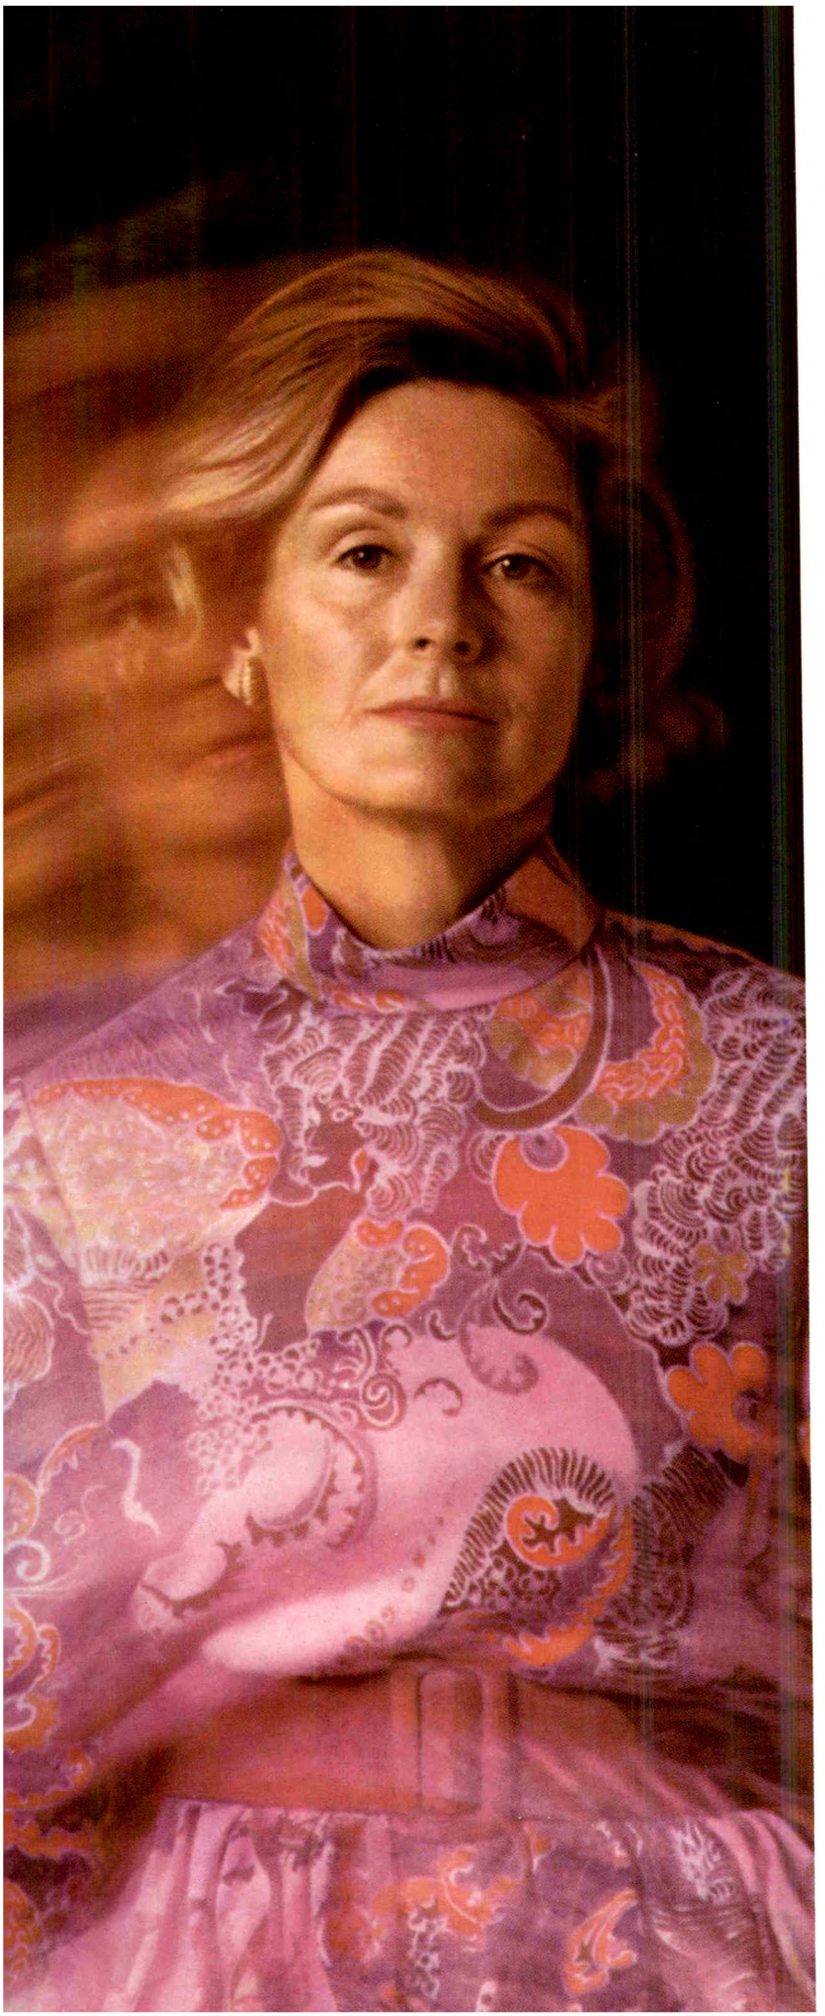
DURATION OF THERAPY: The daily, uninterrupted administration of ANTABUSE must be continued until the patient is fully recovered socially and a basis for permanent self-control is established. Depending on the individual patient, maintenance therapy may be required for months or even years.

TRIAL WITH ALCOHOL: During early experience with ANTABUSE, it was thought advisable for each patient to have at least one supervised alcohol-drug reaction. More recently, the test reaction has been largely abandoned. Furthermore, it should never be administered to a patient over 50 years of age. A clear, detailed, and convincing description of the reaction is felt to be sufficient in most cases.

However, where a test reaction is deemed necessary, the suggested procedure is as follows:



After the first one to two weeks' therapy with 500 mg. daily, a drink of 15 cc. (½ oz.) of 100 proof whiskey or equivalent is taken slowly. This test dose of alcoholic beverage may be repeated once only so that the total dose does not exceed 30 cc. (1 oz.) of whiskey. Once a reaction develops, no more alcohol should be consumed. Such tests should be carried out only when the patient is hospitalized, or comparable supervision and facilities, including oxygen, are available.



MANAGEMENT OF ANTABUSE (DISULFIRAM)-ALCOHOL REACTION: In severe reactions, whether caused by an excessive test dose or by the patient's unsupervised ingestion of alcohol, supportive measures to restore blood pressure and treat shock should be instituted. Other recommendations include: oxygen, carbogen (95 per cent oxygen and 5 per cent carbon dioxide), vitamin C intravenously in massive doses (1 Gm.), and ephedrine sulfate. Antihistamines have also been used intravenously. Potassium levels should be monitored particularly in patients on digitalis since hypokaliemia has been reported.

HOW SUPPLIED: No. 809—Each tablet (scored) contains 250 mg. disulfiram, in bottles of 100. No. 810—Each tablet (scored) contains 500 mg. disulfiram in bottles of 50 and 1,000.

(desipramine hydrochloride NF)
an antidepressant that brings things into focus—promptly
FROM THE NEW
USV
USV Pharmaceutical Corp.
Tuckahoe, N.Y. 10707

Pertofrane®
(desipramine hydrochloride)

Indication: For relief of mental depression.
Contraindications: Do not use MAO inhibitors concomitantly or within 2 weeks of the use of this drug. Hyperpyretic crises or severe convulsive seizures may occur with such combinations; potentiation of adverse reactions can be serious or even fatal. When substituting Pertofrane in patients receiving an MAO inhibitor, allow an interval of at least 14 days. Initial dosage in such patients should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated following recent myocardial infarction and in patients with a known hypersensitivity to tricyclic antidepressants. **Warnings:** Activation of psychosis may occasionally be observed in schizophrenic patients. Due to atropine-like effects and sympathomimetic potentiation, use only with the greatest care in patients with narrow-angle glaucoma or urethral or ureteral spasm. Do not use in patients with the following conditions unless the need outweighs the risk: severe coronary heart disease with EKG abnormalities, progressive heart failure, angina pectoris, paroxysmal tachycardia and active seizure disorder (may lower seizure threshold). This drug may block the action of the antihypertensive, guanethidine, and related adrenergic neuron-blocking agents. Hypertensive episodes have been observed during surgery. The concurrent use of other central nervous system drugs or alcohol may potentiate adverse effects. Since many such drugs may be used during surgery, desipramine should be discontinued prior to elective procedures. Caution patients on the possibility of impaired ability to operate a motor vehicle or dangerous machinery. Do not use in women who are or may become pregnant, or in children under 12 years of age, unless the clinical situation warrants the potential risk. Because of increased sensitivity to the drug, use lower than normal dosage in adolescent and geriatric patients. **Precautions:** Potentially suicidal patients require careful supervision and protective measures during therapy. Prescriptions should be limited to small quantities. Discontinuation of the drug may be necessary in the presence of increased agitation and anxiety shifting to hypomanic or manic excitement. Atropine-like effects may be more pronounced (e.g. paralytic ileus) in susceptible patients and in those receiving anticholinergic drugs (including antiparkinsonism agents). Prescribe cautiously in hyperthyroid patients and in those receiving thyroid medications; transient cardiac arrhythmias have occurred in rare instances. Periodic blood and liver studies should supplement careful clinical observations in all patients undergoing extended courses of therapy. **Adverse Reactions:** The following have been reported: *Nervous System:* dizziness, drowsiness, insomnia, headache, disturbed visual accommodation, tremor, unsteadiness, tinnitus, paresthesias, changes in EEG patterns, epileptiform seizures, mild extrapyramidal activity, falling and neuromuscular incoordination. A confusional state (with such symptoms as hallucinations and disorientation), particularly in older patients and at higher dosage, may require discontinuation of the drug. *Gastrointestinal Tract:* anorexia, dryness of the mouth, nausea, epigastric distress, constipation and diarrhea. *Skin:* skin rashes (including photosensitization), perspiration and flushing sensations. *Liver:* rare cases of transient jaundice (apparently of an obstructive nature) and liver damage. If jaundice or abnormalities in liver function tests occur, discontinue the drug and investigate. *Blood Elements:* bone-marrow depression, agranulocytosis, thrombocytopenia and purpura. If these occur, discontinue the drug. Transient eosinophilia has been observed. *Cardiovascular System:* orthostatic hypotension and tachycardia. Carefully supervise patients requiring concomitant vasodilating therapy, particularly during initial phases. *Genitourinary System:* urinary frequency or retention and impotence. *Endocrine System:* occasional hormonal effects, including gynecomastia, galactorrhea and breast enlargement, and decreased libido and estrogenic effect. *Sensitivity:* urticaria and rare instances of drug fever and cross-sensitivity with imipramine.
Dosage: All patients except geriatric and adolescent: 50 mg. t.i.d. (150 mg. daily). Dosage may be increased up to 200 mg. daily. Geriatric and adolescent patients should usually be started with lower dosage (25 to 50 mg. daily) and may not tolerate higher doses. Dosage may be increased up to 100 mg. daily. Lower maintenance dosages should be continued for at least 2 months after obtaining a satisfactory response. Mild anxiety and agitation which may accompany depression usually remit as the depression responds. Occasionally, however, a sedative or tranquilizer may be indicated. **How Supplied:** 25 mg. capsules (pink) and 50 mg. capsules (maroon and pink), bottles of 100 and 1000; single-dose blister packs, boxes of 500.

USV Pharmaceutical Corp., Tuckahoe, N.Y. 10707

The hostile patient.

He vacillates from suspiciousness to rage.
His disorientation is apparent through
his erratic outbursts against imagined enemies.

His irrational behavior worries his family.
And hinders your treatment.
How do you reach him?

Very possibly, with QUIDE (piperacetazine).

Clinical studies of schizophrenic patients on a regimen of QUIDE have demonstrated moderate to excellent improvement in mental status and remission of hyperactive, combative behavior. Improvement in interpersonal relationships and adjustment to therapy were especially notable.

In clinical evaluation, although extrapyramidal reactions did occur, the low incidence of these reactions allowed for patient cooperation.

When Parkinsonism did occur, it was easily controlled by modification of dosage or, infrequently, the addition of an anti-Parkinson agent. Photosensitivity rarely occurred.

QUIDE (piperacetazine) . . . it may well be what some of your patients are waiting for.

Quide® tablets
piperacetazine

DOW **DOW PHARMACEUTICALS** The Dow Chemical Company Indianapolis, Indiana

See next page for complete prescribing information.

Quide® tablets piperacetazine

DESCRIPTION: QUIDE (piperacetazine) is a piperidine derivative of phenothiazine.

Piperacetazine has the following chemical designation: 10- { 3-[4-(2-Hydroxyethyl)-piperidino]propyl } phenothiazin-2-yl Methyl Ketone.

ACTIONS: The exact mode of action of the phenothiazines is unclear, but drugs of this class produce changes at all levels of the central nervous system, as well as on multiple organ systems.

INDICATIONS: QUIDE is indicated for use in the management of the manifestations of psychotic disorders.

CONTRAINDICATIONS: QUIDE is contraindicated in patients who are comatose or markedly depressed from any cause and in the presence of preexisting thrombocytopenia and other blood dyscrasias, bone marrow depression and in patients with significant liver disease. QUIDE is contraindicated in women who are or may become pregnant since animal reproductive studies adequate to establish safety during pregnancy have not been carried out. QUIDE is contraindicated in patients who have shown hypersensitivity to the drug. Cross sensitivity between phenothiazine derivatives may occur.

WARNING: Like other phenothiazines, QUIDE may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, patients should be cautioned accordingly. Concomitant use with alcohol should be avoided due to the potential additive effect. Patients with known suicidal tendencies should not be given QUIDE except under strict medical supervision.

Use in Children: The use of QUIDE in children under 12 years of age is not recommended because safe conditions for its use have not been established.

PRECAUTIONS: Use with caution in persons who:

1. are receiving barbiturates or narcotics, because of additive effects on central nervous system depression. The dosage of the narcotic or barbiturate should be reduced when given concomitantly with QUIDE.
2. are receiving atropine or related drugs, because of additive anticholinergic effects.
3. have a history of epilepsy, because this drug may lower the convulsive threshold. Adequate anticonvulsant therapy must be maintained concomitantly.
4. are exposed to extreme heat or phosphorous insecticides.
5. have a history of peptic ulcer. Aggravation of preexisting ulcer has occurred.
6. have cardiovascular disease.
7. have respiratory impairment due to acute pulmonary infections or chronic respiratory disorders such as severe asthma or emphysema.

Keep in mind that the antiemetic effect may mask the toxicity of other drugs or obscure the diagnosis of such conditions as intestinal obstruction or brain tumor.

Any sign of blood dyscrasias requires immediate discontinuance of the drug and the institution of appropriate therapy.

The possibility of liver damage, pigmentary retinopathy, lenticular or corneal deposits, and development of irreversible dyskinesias should be kept in mind when patients are on prolonged therapy.

Abrupt Withdrawal: In general, phenothiazines do not produce psychic dependence, but gastritis, nausea and vomiting, dizziness and tremulousness have been reported following abrupt cessation of high-dose therapy. Reports suggest that these symptoms can be reduced if concomitant antiparkinson agents are continued for several weeks after the phenothiazine is withdrawn.

ADVERSE REACTIONS: Not all of the following adverse reactions have been reported with QUIDE (piperacetazine), but pharmacological similarities among various phenothiazine derivatives require that each be considered.

Note: Sudden Death has occasionally been reported in patients who have received phenothiazines. In some cases death was apparently due to cardiac arrest, in others the cause appeared to be asphyxia due to failure of the cough reflex. In some patients the cause could not be determined, nor could it be established that death was due to the phenothiazine.

Drowsiness: May occur particularly during the first or second week, after which it generally disappears. If troublesome, lower the dosage.

Jaundice: Incidence is low. When it occurs (usually between the second and fourth weeks of therapy) it is generally regarded as a sensitivity reaction. The clinical picture resembles infectious hepatitis with laboratory features of obstructive jaundice. It is usually reversible although chronic jaundice has been reported with phenothiazine therapy.

Hematological Disorders: Agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenia purpura and pancytopenia.

Agranulocytosis: Most cases have occurred between the fourth and tenth weeks of therapy. Patients should be watched closely during that period for the sudden appearance of sore throat or other signs of infection. If white blood count and differential show significant cellular depression, discontinue the drug and start appropriate therapy. A slightly lowered white count, however, is not in itself an indication to discontinue the drug.

Cardiovascular: Postural hypotension, tachycardia (especially following rapid increase in dosage), bradycardia, cardiac arrest, faintness and dizziness. Occasionally the hypotensive effect may produce a shock-like condition. In the event a vasoconstrictor is required, levarterenol and phenylephrine are the most suitable. Other pressor agents, including epinephrine, should not be used because a paradoxical further lowering of the blood pressure may ensue.

EKG changes, nonspecific, usually reversible, have been observed in some patients receiving phenothiazine tranquilizers. Their relationship to myocardial damage has not been confirmed.

CNS Effects: Neuromuscular (extrapyramidal) Reactions: These are usually dose related and take three forms: (1) pseudoparkinsonism; (2) akathisia; and (3) dystonias (Dystonias include spasms of the neck muscles, extensor rigidity of back muscles, carpopedal spasm, eyes rolled back, convulsions, trismus and swallowing difficulties). These resemble serious neurological disorders but usually subside within 48 hours. Management of the extrapyramidal symptoms, depending upon the type and severity, includes sedation, injectable diphenhydramine, and the use of antiparkinsonism agents.

Hyperreflexia has been reported in the newborn when a phenothiazine was used during pregnancy.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, tardive dyskinesia may appear in some patients on long-term therapy or may appear after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of the mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia; anti-parkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time the syndrome may not develop.

Other CNS Effects: Cerebral edema. Abnormality of cerebral spinal fluid proteins. Convulsive seizures, particularly in patients with EEG abnormalities or a history of such disorders. Hyperpyrexia.

Adverse Behavioral Effects: Paradoxical exacerbation of psychotic symptoms.

Allergic Reactions: Urticaria, itching, erythema, photosensitivity (avoid undue exposure to the sun), eczema. Severe reactions include: exfoliative dermatitis (rare); contact dermatitis in nursing personnel administering the drug; asthma; laryngeal edema; angioneurotic edema; and anaphylactoid reactions.

Endocrine Disorders: Lactation and moderate breast engorgement in females and gynecomastia in males on large doses; changes in libido; false-positive pregnancy tests; amenorrhea; hyperglycemia, hypoglycemia, glycosuria.

Autonomic Reactions: Dry mouth, nasal congestion, constipation, adynamic ileus, myosis, mydriasis, urinary retention.

Special Considerations in Long-term Therapy: After prolonged administration of phenothiazines, pigmentation of the skin has occurred chiefly in the exposed areas, especially in females on large doses. Ocular changes consisting of deposition of fine particulate matter in the cornea and lens, progressing in more severe cases to star-shaped lenticular opacities; epithelial keratopathies; pigmentary retinopathy.

Other Adverse Reactions: Increases in appetite and weight; peripheral edema.

DOSAGE AND ADMINISTRATION: Dosage should be individualized, not only initially but during the course of therapy, and the minimal effective dose should always be employed. A starting dosage of 10 mg. two to four times daily is recommended for adults. The dose may be increased up to 160 mg. daily within a three to five day period. Should side effects occur, dosage should be reduced or discontinued as indicated. For maintenance therapy, up to 160 mg. daily in divided doses may be given.

OVERDOSAGE WITH PHENOTHIAZINES:
Manifestations: One of three clinical pictures may be seen.

1. Extreme somnolence; patient can usually be roused with prodding, but if permitted will fall asleep. General condition is usually satisfactory. The skin, though pale, is warm and dry. Slight blood pressure, respiratory and pulse changes may occur but are not problems.
2. Mild to moderate drop in blood pressure (patient may be conscious or unconscious). Skin is markedly gray but warm and dry. Nail beds are pink. Respiration is slow and regular. Pulse is strong but rate slightly increased.
3. Severe hypotension, possibly accompanied by weakness, cyanosis, perspiration, rapid thready pulse and respiratory depression.

Treatment: Is essentially symptomatic and supportive. Early gastric lavage and intestinal purges may help. Centrally acting emetics may not help because of the possible antiemetic effect of QUIDE. Give hot tea or coffee. Severe hypotension usually responds to measures described under hypotensive effects (see ADVERSE REACTIONS: *Cardiovascular*). Additional measures include pressure bandages to lower limbs, oxygen and I.V. fluids.

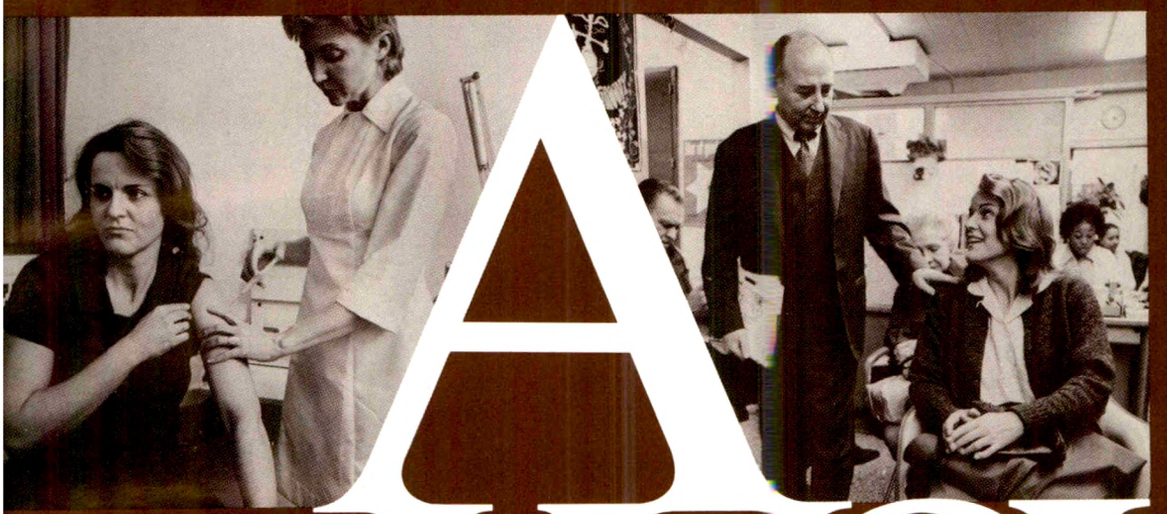
Avoid stimulants that may cause convulsions (e.g., picrotoxin and pentylenetetrazol).

Limited experience with dialysis indicates that it is not helpful.

CAUTION: Federal law prohibits dispensing without prescription.

HOW SUPPLIED:

QUIDE (piperacetazine) Tablets—10 mg. (orange)—bottles of 100 (NDC 183-52-2), and bottles of 1000 (NDC 183-52-4).



QUIDE (piperacetazine) Tablets—25 mg. (yellow)—bottles of 100 (NDC 183-53-2), and bottles of 1000 (NDC 183-53-4).

Note: Dispense only in light-resistant containers; the coatings on these tablets contain light-sensitive colors.

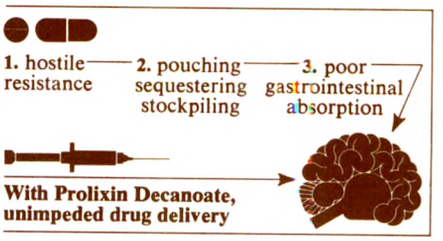
For schizophrenic patients...

A way out:

...that helps keep them out

Controlled Drug Delivery

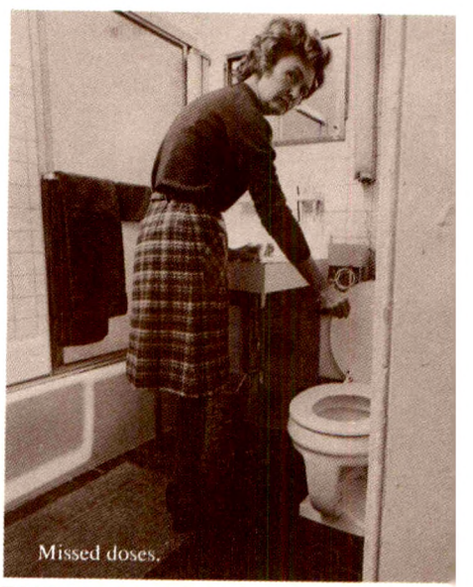
with new



PROLIXIN® DECANOATE
(FLUPHENAZINE DECANOATE INJECTION)

Puts control of the schizophrenic in your hands with injections 1 to 3 weeks apart or longer with an average duration of effect of about 2 weeks

Controlled drug delivery—a revolution in patient management



PROLIXIN® DECANOATE (Fluphenazine Decanoate Injection) HELPS ASSURE EFFECTIVE, UNHINDERED MEDICATION

Controlled drug delivery is *physician*-controlled delivery, an effective prophylactic maneuver against disruption of therapy—one of the most common causes of psychotic relapse. Is the patient taking his medication? You know because you administer it or direct others to. Once administered, therapy cannot be altered by the patient, by his family, or by anyone else.

In most patients, symptomatology is controlled by Prolixin Decanoate for periods of two weeks with a single injection. Sequestered medication and similar problems associated with oral therapy are not encountered. Nor does the patient risk drug loss through severe diarrhea or poor gastrointestinal absorption. Prolixin Decanoate keeps the patient medicated...helps make him more amenable to the entire treatment program and improves his chances for rehabilitation and discharge.

The outpatient is vulnerable to the dictates of his own poor judgment. Deluded by a sense of well-being, he may question the need for medication. Family and friends often give him misleading advice. Oral therapy in such a patient encourages missed doses. Medication with Prolixin Decanoate (Fluphenazine Decanoate Injection) helps assure drug delivery when required and in the dosage prescribed. It helps keep the outpatient out.

FOUR REASONS FOR READMISSION...

For brief summary, see last page of this presentation.

)LIXIN® DECANOATE
phenazine Decanoate Injection)
URES ECONOMIC DRUG
LIVERY...LESS FREQUENT
SING THAN WITH ORAL
ERAPY

ontrolled drug delivery brings cost
ıerapy down with less hospitaliza-
, less nursing time, less frequent
ng. Low annual dosage means less
for the hospital, for the patient's
ily, and for the community. It
ns a minimum of drug holidays to
d long-term complications, with
· confusing schedules for patient
family.

trolled drug delivery—
volution in the treatment of the
zophrenic patient

)LIXIN® DECANOATE
phenazine Decanoate Injection)
LPS ENHANCE LIKELIHOOD
DISCHARGE

)ptimally, the mental hospital
ıld be a rehabilitating bridge be-
n life before and life after custo-
care. Prolixin Decanoate often
tens that bridge because getting the
tient out is frequently a matter of
)ing him medicated. And 1 injec-
of Prolixin Decanoate means ap-
ximately 2 weeks of symptom
rol. The importance of control by
physician with this injectable can
een in the fact that about 1 out of
y 5 inpatients does not take his tab-
even when they are administered by nursing staff. With controlled drug delivery, lost or hidden doses are not a problem.

In one study,[1] 24 chronic long-term hospital patients were treated with Prolixin Decanoate in dosages of 12.5 mg. to 75 mg. given every 7 days to 3 weeks. Most of the patients received 25 to 50 mg. per injection. Of these, 13 were discharged after 6 months of treatment, 4 were considered dischargeable, and 7 did not improve. In 12 of the 24 patients who previously had been on different psychotropic drugs for periods of 4 to 96 weeks, improvement with Prolixin Decanoate (Fluphenazine Decanoate Injection) was observed in affect, volition, and higher mental functions. Dischargeability in these patients "may also have been enhanced because the staff, the patient, and the family were assured of an adequate and regular medication intake."[1]

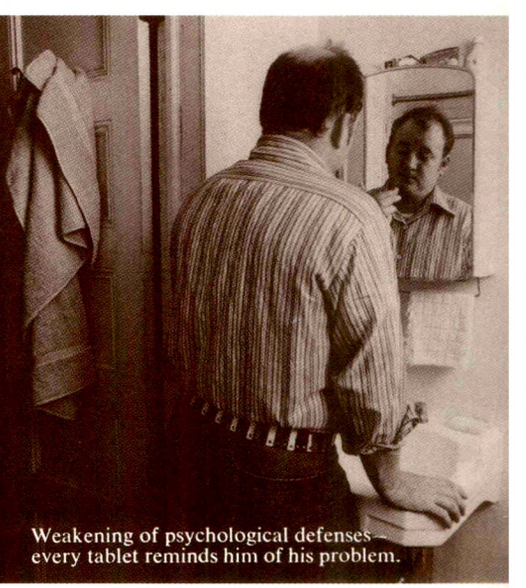
Controlled drug delivery—
a revolution in the care of the outpatient

PROLIXIN® DECANOATE
(Fluphenazine Decanoate Injection)
PROMOTES CONTINUITY OF MEDICATION WITH DIMINISHED LIKELIHOOD OF RELAPSE COMPARED WITH ORAL THERAPY

Success in rehabilitative areas like employment and social acceptance depends in large measure on adequate and continuing phenothiazine intake; success in family adjustment no less so. Short-acting medication is not the best path to such success. According to one report,[2] "approximately 50% of all discharged psychotic patients fail to take even the first dose of their outpatient medication." And McClellan and Cowan[3] state that a substantial number of patients taking antipsychotic drugs do so in amounts significantly less than those prescribed. Even once-daily administration does not solve the problem of poor home supervision or the patient's lack of insight into his condition.

Controlled drug delivery with Prolixin Decanoate (Fluphenazine Decanoate Injection) is an efficient route to continuity of medication, and therefore to long-term remission. For one thing there is less strain on the patient's often tenuous adjustment to family living. Since family members are not responsible for supervising the patient's medical needs, they tend to be more accepting, and better feeling is promoted merely because the controlled delivery regimen demonstrates that improvement is possible. Controlled drug delivery also strengthens the patient's psychological defenses. He is not reminded of his psychiatric illness by multiple daily doses.

The same unique advantages of controlled drug delivery with Prolixin Decanoate that promote the discharge-



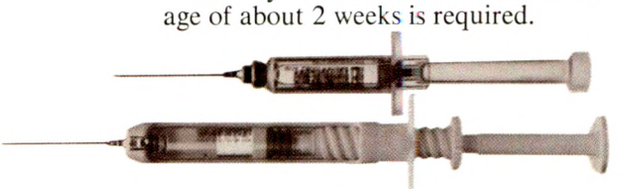
(Continued on following page)

kpiling.

Misleading advice from family and friends.

Weakening of psychological defenses—every tablet reminds him of his problem.

)D REASONS FOR CONTROLLED DRUG DELIVERY



(Continued from preceding page)
ability of the inpatient and help maintain him in the community are true for the patient who has never been hospitalized. It is just these advantages that will help the physician or psychiatrist keep him in the community without the need for custodial care.

Controlled drug delivery—a revolution in efficiency of administration

PROLIXIN® DECANOATE (Fluphenazine Decanoate Injection) SAVES TIME, REDUCES COST IN THE HOSPITAL, CLINIC, OFFICE

Controlled drug delivery saves time, reduces costs in the hospital. With Prolixin Decanoate there can be no palming, pouching, regurgitating. With Prolixin Decanoate resistance to therapy dwindles. With symptoms controlled, the patient is more manageable, more comfortable, more amenable to the total hospital treatment program. With Prolixin Decanoate only 1 dose visit every 1 to 3 weeks with an average of about 2 weeks is required.

Controlled drug delivery saves time, reduces costs in the clinic and office.

With Prolixin Decanoate less frequ dosing. With Prolixin Decanoate (phenazine Decanoate Injection) n patients report for their injections c once in every 2-week period.

PROLIXIN® DECANOATE

(FLUPHENAZINE DECANOATE INJECTION)

IEF SUMMARY

lixin Decanoate (Fluphenazine Decanoate ction) provides 25 mg. fluphenazine deca- te per cc. in a sesame oil vehicle with % (w/v) benzyl alcohol as a preservative.

NTRAINDICATIONS: In presence of sus- ted or established subcortical brain dam- . In patients who have a blood dyscrasia, r damage or renal insufficiency, or who are iving large doses of hypnotics, or who are natose or severely depressed. In patients o have shown hypersensitivity to fluphena- e; cross-sensitivity to phenothiazine deriva- s may occur.

Not intended for use in children under 12.

RNINGS: Mental and physical abilities re- ed for driving a car or operating heavy chinery may be impaired by use of this g. Physicians should be alert to the possi- ty that severe adverse reactions may occur ich require immediate medical attention. entiation of effects of alcohol may occur. ety for use during pregnancy has not been ablished; weigh possible hazards against ential benefits if administered during gnancy.

ECAUTIONS: Caution must be exercised nother phenothiazine compound caused olestatic jaundice, dermatoses or other al- gic reactions because of the possibility of ss-sensitivity. When psychotic patients on ge doses of a phenothiazine drug are to un- go surgery, hypotensive phenomena should watched for; less anesthetics or central ner- us system depressants may be required. Be- se of added anti-cholinergic effects, fluphen- ne may potentiate the effects of atropine.

Use fluphenazine decanoate cautiously in ients exposed to extreme heat or phospho- insecticides; in patients with ulcer disease tory since aggravation of peptic ulcer has urred; in patients with history of convul- e disorders since grand mal convulsions ve occurred; and in patients with special dical disorders such as mitral insufficiency other cardiovascular diseases, and pheo- romocytoma. Bear in mind that with pro- nged therapy there is the possibility of liver mage, pigmentary retinopathy, lenticular d corneal deposits, and development of irre- sible dyskinesia.

Fluphenazine decanoate should be adminis- ed under the direction of a physician experi- ced in the clinical use of psychotropic drugs. riodic checking of hepatic and renal func- ns and blood picture should be done. Renal nction of patients on long-term therapy ould be monitored; if BUN becomes abnor- al, treatment should be discontinued. "Silent eumonias" are possible.

DVERSE REACTIONS: *Central Nervous stem*—Extrapyramidal symptoms are most frequently reported. These include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, and hyperreflexia; most often these are reversible, but they may be persistent. One can expect a higher incidence of such reactions with fluphenazine decanoate than with less potent piperazine derivatives or straight-chain phenothiazines. The incidence and severity will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of anti-parkinsonian drugs such as benztropine mesylate or intravenous Caffeine and Sodium Benzoate Injection U.S.P., and by subsequent reduction in dosage. A persistent and sometimes irreversible pseudo-parkinsonian syndrome may develop with chronic administration of phenothiazine compounds. Rhythmic, stereotyped dyskinetic involuntary movements, particularly of the face, mouth, tongue and jaw occur, and may be accompanied by choreiform movements of the limbs. The symptoms persist after drug withdrawal. Antiparkinsonian agents are seldom of benefit. The risk appears to be greatest in elderly females with organic brain damage receiving large and prolonged doses. Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams and reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may have to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection U.S.P. is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.

Hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines. Local tissue reactions occur only rarely with injections of fluphenazine decanoate.

For full prescribing information, consult package insert.

Supply: 1 cc. Unimatic® single dose preassembled syringes and cartridge-needle units, and 5 cc. vials.

DEPARTMENT OF HEALTH PROVINCE OF NEWFOUNDLAND CANADA

PSYCHIATRISTS

Two psychiatrists required as full time consultants in the Division of Mental Health Services, St. John's. One position is in the forensic-correctional field and the other in the disorders of children.

These are challenging positions with opportunities to provide consultation in program development in a wide range of services in voluntary agencies, hospitals, educational settings and government departments. There is a possibility, also, for involvement in clinical work, teaching and research.

Salary is negotiable.

Full public service benefits apply with generous annual and sick leave with pay, provincial statutory holidays and contributory pension plan. Financial assistance towards relocation is available.

Applications and/or requests for further information should be addressed to:

Child Psychiatrist

Director – Out-Patient Services $28,000-$32,100

(contract employment negotiable at attractive rates)

The Thistletown Regional Centre for Children and Adolescents, MINISTRY OF HEALTH, is located in northwest Toronto and is an affiliated teaching setting for the University of Toronto, approved for psychiatric training by the Royal College.

The Centre provides out-patient, day treatment, and residential treatment for emotionally disturbed children and adolescents.

The out-patient facility, besides providing screening for out-patient treatment for children and adolescents and their families, is committed to community consultation, education and research.

Applicants must have a licence to practise medicine in Ontario and certification in psychiatry (R.C.P.S. of Canada), or comparable specialist standing.

Please apply to: Clinical Director, 11 Farr Avenue, Rexdale, Ontario M9V 2A5.

Information on other medical positions may be obtained by writing to the above address.

ONTARIO
PROVINCE OF OPPORTUNITY

PSYCHIATRISTS: $32,400–$40,800

The Northeastern Regional Mental Health Centre, located in South Porcupine, has positions available for qualified psychiatrists who wish to consider professionally challenging participation in multidisciplinary community oriented programs. These appointments are on a contract basis for one or two years.

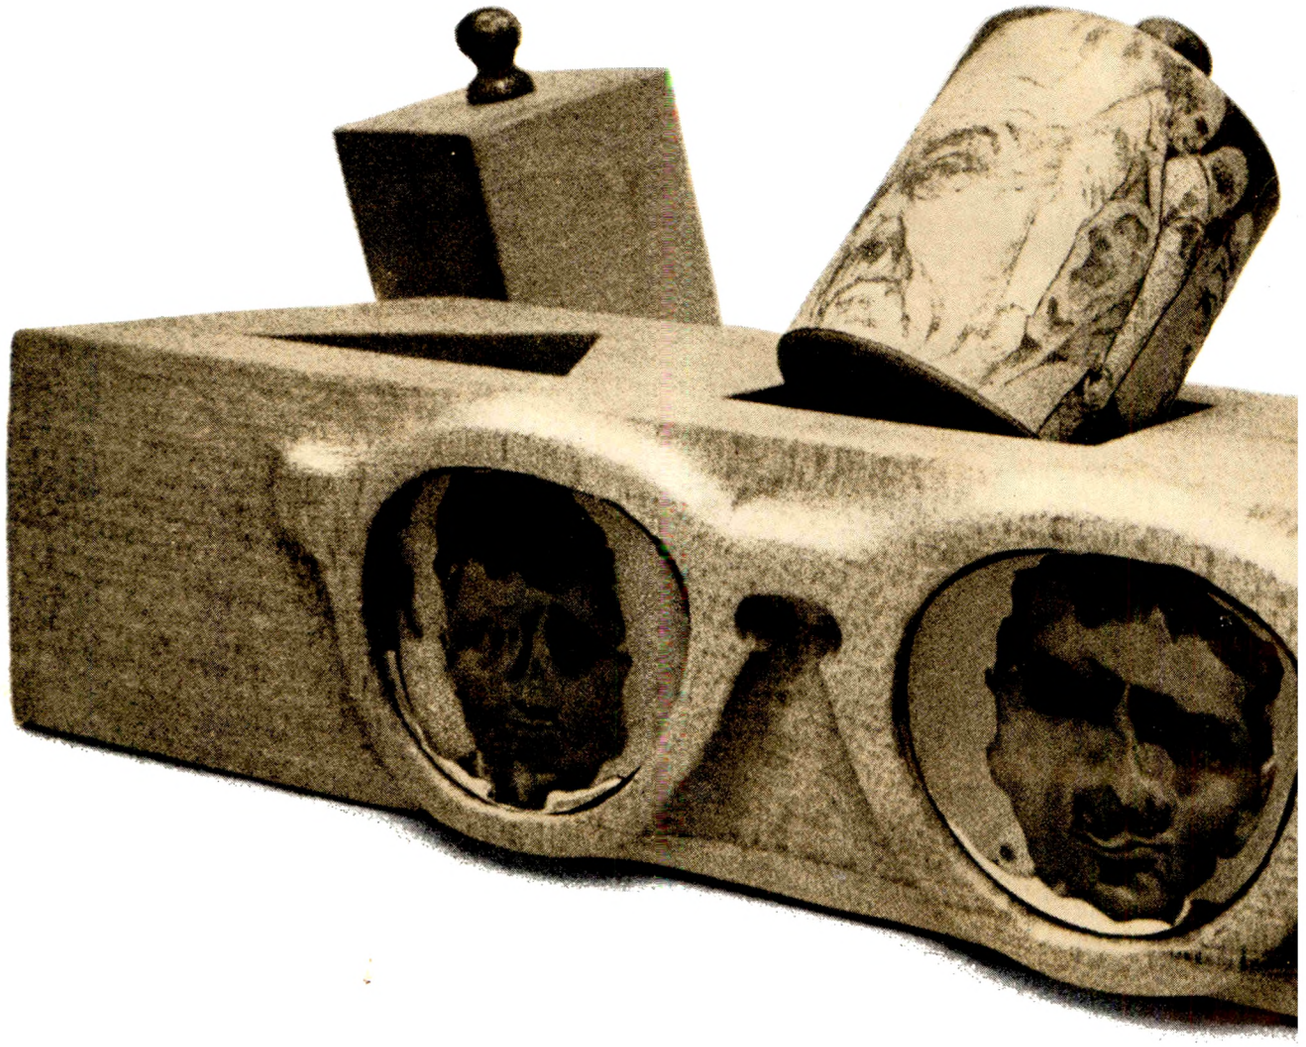
The Centre offers a comprehensive range of services for adult psychiatric patients, emotionally disturbed children and adolescents, and the mentally retarded. Innovative and creative programs are being developed to meet the particular needs of the population of Northern Ontario.

Qualifications: Registration as a medical practitioner by the College of Physicians and Surgeons of Ontario, either by full registration or enrolment on the Special Register and certification in psychiatry from the R.C.P.S. (Canada) OR specialist standing in another jurisdiction acceptable as comparable to this certificate.

Benefits: Four weeks annual vacation and fifteen days sick leave.

Qualified psychiatrists are invited to submit their applications as soon as possible to: **The Administrator, Northeastern Regional Mental Health Centre, P.O. Box 1720, South Porcupine, Ontario, Canada.**

ONTARIO
PROVINCE OF OPPORTUNITY



PSYCHIATRIC RESIDENTS

Opening for psychiatric residents in accredited General Hospital, adult, adolescent and child psychiatric services with in- and out-patient departments. Comprehensive didactic program by members of the staff. Salary according to qualifications. These residencies are approved by the University and recognized as part of the McGill University Diploma Course.

Please apply to:

S. H. Knox,
Executive Director,
Lakeshore General Hospital,
Pointe Claire, P.Q.

H l- impro yoU. d pr d patients' ability to cope.

In Brief:

Actions: Norpramin® (desipramine hydrochloride) is an antidepressant drug of the tricyclic type. It has been found in some studies to have a more rapid onset of action than imipramine; antidepressant efficacy is similar though potency on a weight basis may be less. The earliest manifestations consist mainly of an increase in psychomotor activity. Full treatment benefit is seldom attained before the end of the second week.

Indications: Norpramin® (desipramine hydrochloride) is indicated for the relief of depressive symptoms. Endogenous depressions are more likely to be alleviated than others.

Contraindications: Desipramine hydrochloride should not be given within two weeks of treatment with a monoamine oxidase inhibitor. Contraindications include the acute recovery period following myocardial infarction and hypersensitivity to the drug. Cross sensitivity with other dibenzazepines is a possibility.

Warnings: 1. Extreme caution should be used in patients: (a) with cardiovascular disease, (b) with a history of urinary retention or glaucoma, (c) with thyroid disease or those on thyroid medication, (d) with a history of seizure disorder. 2. This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. 3. *Use in Pregnancy:* Safe use during pregnancy and lactation has not been established. 4. *Use in Children:* Norpramin® (desipramine hydrochloride) is not recommended for use in children. 5. This drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. Therefore, the patient should be cautioned accordingly.

Precautions: This drug should be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with drugs of this class. It should be kept out of reach of children. Reduce dosage, or alter treatment, if serious adverse effects occur. Norpramin® (desipramine hydrochloride) therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates and may cause exacerbation of psychosis in schizophrenic patients. Close supervision and careful adjustment of dosage are required when this drug is given along with anticholinergic or sympathomimetic drugs. While taking this drug, response to alcoholic beverages may be exaggerated. There is limited clinical experience in the concurrent administration of ECT and antidepressant drugs; thus, one should consider the possibility of increased risk relative to benefits. Discontinue as soon as possible prior to elective surgery because of possible cardiovascular effects. Hypertensive episodes have been observed during surgery in patients on desipramine hydrochloride. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is neutropenia.

Adverse Reactions: *Cardiovascular:* hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke. *Psychiatric:* confusional states (especially

Coping with Depression

The ability to cope with depressive illness, for the patient and to some degree for the physician, largely depends on hope—a crutch that is usually lacking in the depressed patient. To the depressed patient all the good things of life are bleak, black, or unattainable; all that is bad has been happening or will happen. Helping such a patient to cope with life again, to overcome the incapacitating moods, outlooks, and fears which characterize depression, can be a most rewarding experience for the physician.

Although Norpramin® (desipramine hydrochloride) is relatively rapid-acting, the patient should be told that he will not feel better immediately but that he will gradually become his old self again. A minor tranquilizer in appropriate dosage may be used with Norpramin temporarily if anxiety due to depression is present; a phenothiazine may be used similarly if agitation is severe.

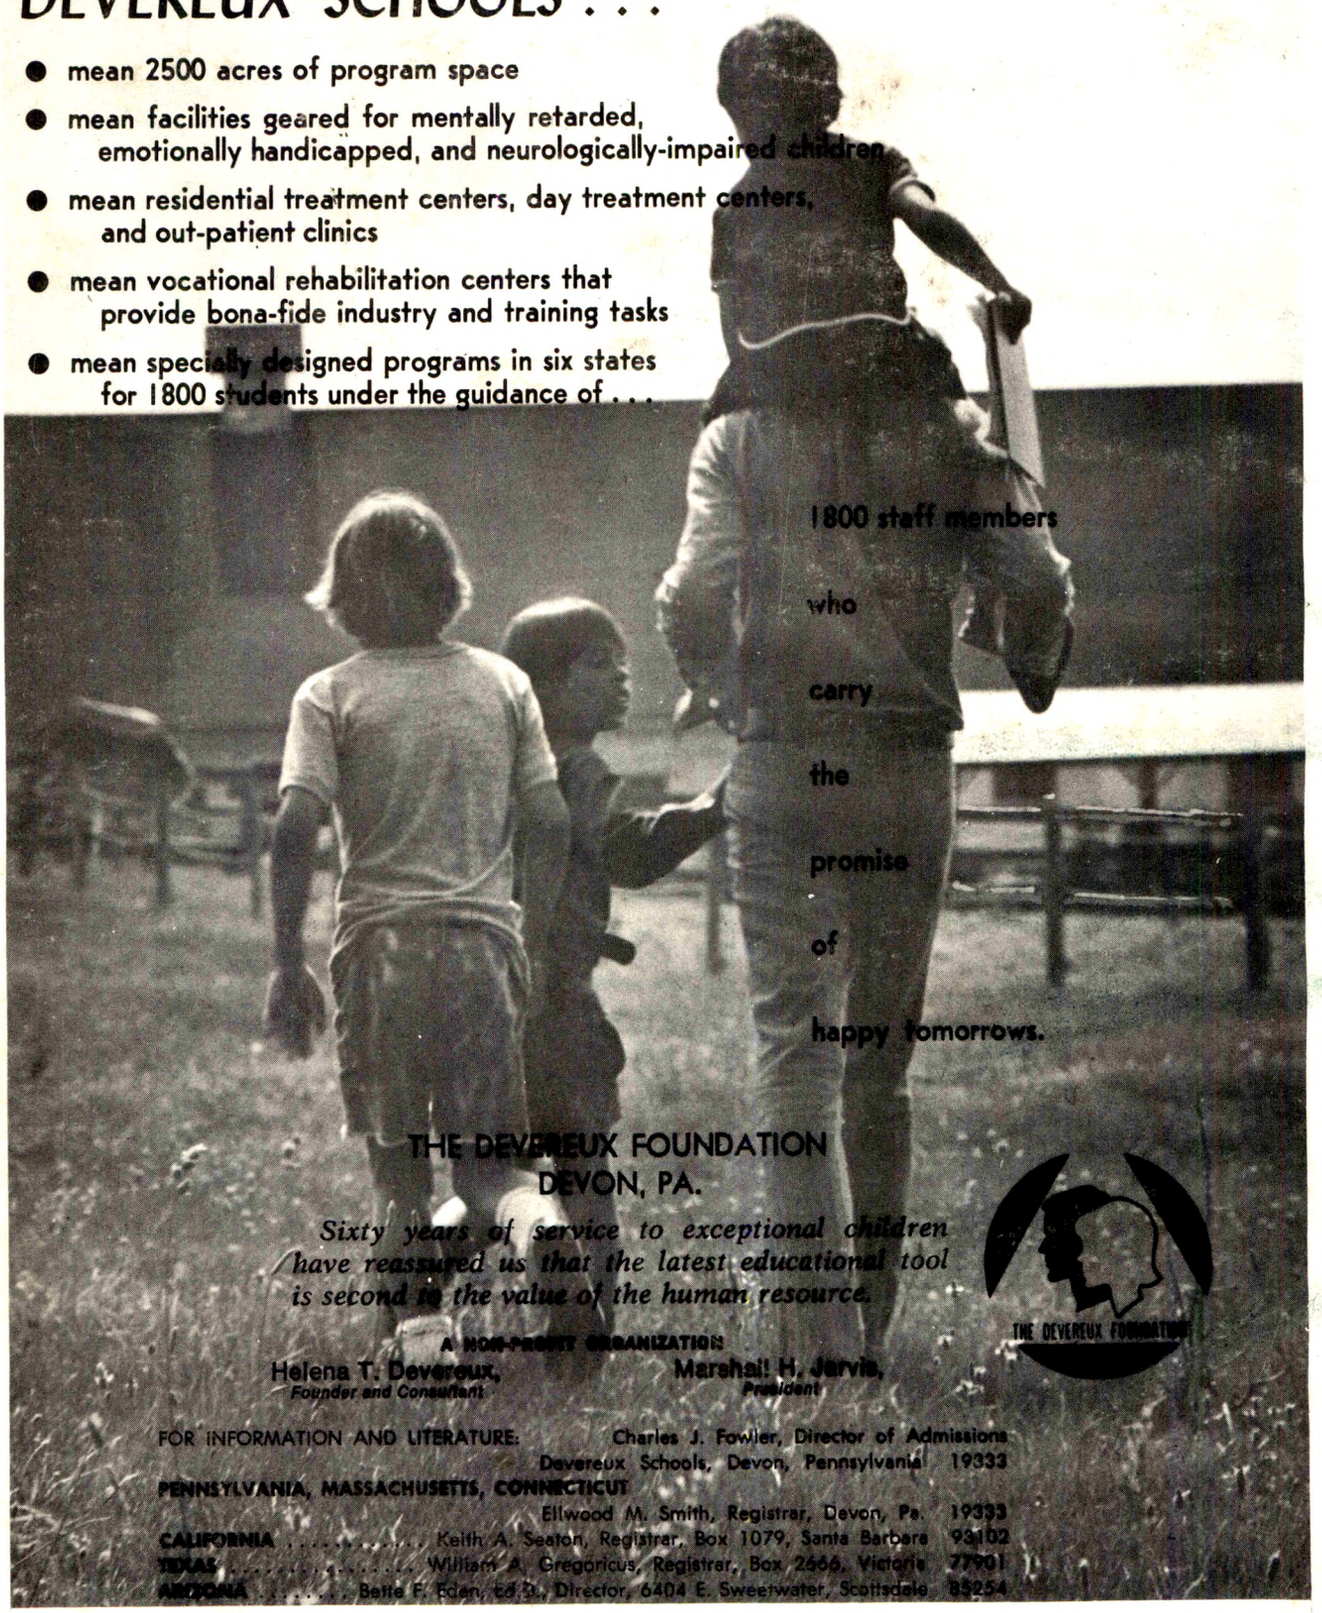
Frequently, Norpramin and your own understanding of the patient are all that is necessary.

Norpramin®
(desipramine hydrochloride)
helps the depressed cope with life again.

in the elderly), hallucinations, disorientation, delusions; anxiety, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis. *Neurological:* paresthesias of extremities; incoordination, ataxia, tremors, peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus. *Anticholinergic:* dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, hypotonic bladder. *Allergic:* skin rash, petechiae, urticaria, itching, photosensitization, edema (of face and tongue or general), drug fever. *Hematologic:* agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue. *Endocrine:* gynecomastia; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels. *Other:* jaundice (simulating obstructive), altered liver function; weight gain or loss; perspiration, flushing; urinary frequency, nocturia; parotid swelling; drowsiness, dizziness, weakness and fatigue, headache; alopecia. *Withdrawal Symptoms:* Though not indicative of addiction, abrupt cessation after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: *The usual adult dose:* 50 mg. three times daily; increase if necessary after 7 to 10 days to maximum of 200 mg. daily. Dosages above 200 mg. per day are not recommended. *Maintenance:* At a lower dose adequate to maintain remission. *Adolescent and geriatric patient dose:* 25 to 50 mg. daily if necessary.

Overdosage: There is no specific antidote for desipramine, nor are there specific phenomena of diagnostic value characterizing poisoning by the drug. The principles of management of coma and shock by means of the mechanical respirator, cardiac pacemaker, monitoring of central venous pressure and regulation of fluid- and acid-base balance are well known in most medical centers. If heart failure is imminent, digitalize promptly.



How Supplied: Norpramin® (desipramine hydrochloride) *25 mg.,* sugar coated tablets, yellow, in bottles of 50, 500 and 1000 tablets. Norpramin® (desipramine hydrochloride) *50 mg.,* sugar coated tablets, light green, in bottles of 50. 250 and 1000 tablets.

Information for Contributors

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in duplicate to Francis J. Braceland, M.D., Editor, *The American Journal of Psychiatry*, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Authors of numbered papers presented at the Association's annual meeting should submit two copies of the manuscript to the secretary of the session or notify the secretary that the manuscript will be sent to the *Journal* office later.

All numbered annual meeting papers become the property of the *Journal* although, due to space limitations, fewer than half can be published in the *Journal*. Release of a manuscript for publication elsewhere must be secured from the Editor.

Communications about a manuscript, by letter or telephone (202-232-7878), should include reference to the manuscript number. In the case of annual meeting papers, this is the number carried in the program booklet; in the case of other manuscripts, it is the number noted in the letter acknowledging receipt of the manuscript.

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material and that they are not being considered for publication elsewhere. Once a paper has been published in the *Journal*, which is a copyrighted publication, the legal ownership of all parts of the paper, including any illustrations, passes from the author to the *Journal*. If an individual or organization wishes to reprint material published in the *Journal*, written permission must first be secured from the Editor or Managing Editor.

Manuscripts are accepted on condition that the Editor be given the right to make revisions aimed at greater conciseness and clarity and to bring the manuscript into conformity with *Journal* style regarding capitalization, punctuation, etc.

The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not reflect the official attitude or position of the American Psychiatric Association or of the *Journal*'s Editorial Board.

SPECIFICATIONS FOR MANUSCRIPTS

Manuscripts should be typed in upper and lower case on one side only of letter-size bond (or other opaque) paper. All parts of the manuscript (including case reports, footnotes, references, etc.) should be double-spaced, with generous margins. Subheads should be inserted at reasonable intervals to aid in comprehension and to break the typographical monotony of lengthy texts. Abbreviations not easily recognized by the average reader should be explained.

Length. As a general rule the manuscript of a regular article should not exceed 10–12 typed pages, unless a special arrangement has been made with the Editor; Brief Communications should not exceed eight typed pages. Letters to the Editor should not exceed 500 words unless a special arrangement has been made with the Editor.

Author identification. The authors' affiliations and position titles should be provided and an address and telephone number given for the first-named author or the co-author who has been designated to handle the galley proofs and reprint requests. The number of authors should preferably not exceed four, with other collaborators being acknowledged in a footnote.

Precis. A brief precis is included at the beginning of each article: 60–100 words for regular articles, 40–60 words for Brief Communications. The author may prepare the precis himself or ask that the *Journal* staff prepare it, in which case the author may make any necessary changes on the galley proofs.

References. References should be typed double-spaced on a separate sheet of paper, to be attached at the end of the manuscript. They should be arranged according to their order of appearance in the text, where they should be indicated by numbers in parentheses. Reference citations should be restricted to closely pertinent papers; a complete review of the literature is rarely desirable, except in the case of review articles for which a special arrangement has been made with the Editor.

References should be typed in accordance with the style shown below for books and journal articles; chapters in books will be treated as journal articles with regard to capitalization. Up to three authors should be listed; one or more authors past the third will be designated "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Schildkraut JJ: Tranylcypromine: effects on norepinephrine metabolism in rat brain. Am J Psychiatry 126:925–931, 1970
3. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349–365, 1967
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968, pp 1–12

Tables and figures. Titles and headings of any tables and figures should be sufficiently clear that the meaning of the data is understandable without reference to the text. See recent issues of the *Journal* for the general requirements of style.

Each table should be typed on a separate sheet, attached at the end of the manuscript. The data should be arranged so that columns of like material read down, not across.

A complete set of figures, preferably in the form of glossy prints, should accompany each of the two copies of the manuscript. Most figures will be reduced to about 3¼ inches in width, the column width of the *Journal*; all elements of a figure should be prepared to withstand this reduction. Graphs should be finished drawings not requiring further artwork. Authors are urged to engage the services of a professional in the preparation of figures. Authors may be required to meet the costs of any further artwork that must be done in the editorial office.

AUTHOR'S CORRECTIONS

Galley proofs will be sent to the first-named author for corrections after the paper has been scheduled for publication; prompt return (preferably within 48 hours of receipt) is necessary to ensure publication in the assigned month. If an author expects to be away from his office for a long period of time after he has received the acceptance letter, he should inform the *Journal* office or arrange with a colleague to read the proofs. Authors are urged to keep changes on galleys to a minimum.

REPRINTS

An order form for reprints will be attached to the galley proofs submitted to authors for correction. Reprints are usually mailed to authors about a month after publication of the article. Requests from others to order reprints should be directed to the Editor; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

PATIENT DATA:
COLLECTION
INDEXING
STORAGE
MANIPULATION
RETRIEVAL
DISPLAY
PLOTTING
CHART GENERATION
AND
AUTOMATIC TYPING

. . . If your activities depend upon the acquisition, organization, maintenance, recall and regeneration of medical data and information . . .

Biomedimation Corporation can provide qualified prospects with trial use of a convenient, low cost and reliable desk-top medical information and patient data management service.

You may subscribe to any or all of these related services:

DATABASE MANAGEMENT—Automated collection, safe storage, manipulation, display and analysis of data and information. Automated information indexing, storage and retrieval. Document reference retrieval.

NETWORK MANAGEMENT—Access to the database from one or more locations.

GRAPHICS MANAGEMENT—Automated letter writing (replaces your MT/ST or MC/ST), journal article drafting, text editing, plotting and chart generation.

EXPERT CONSULTATION—Biostatistical, experimental design, forms design, and information indexing support; and personnel training.

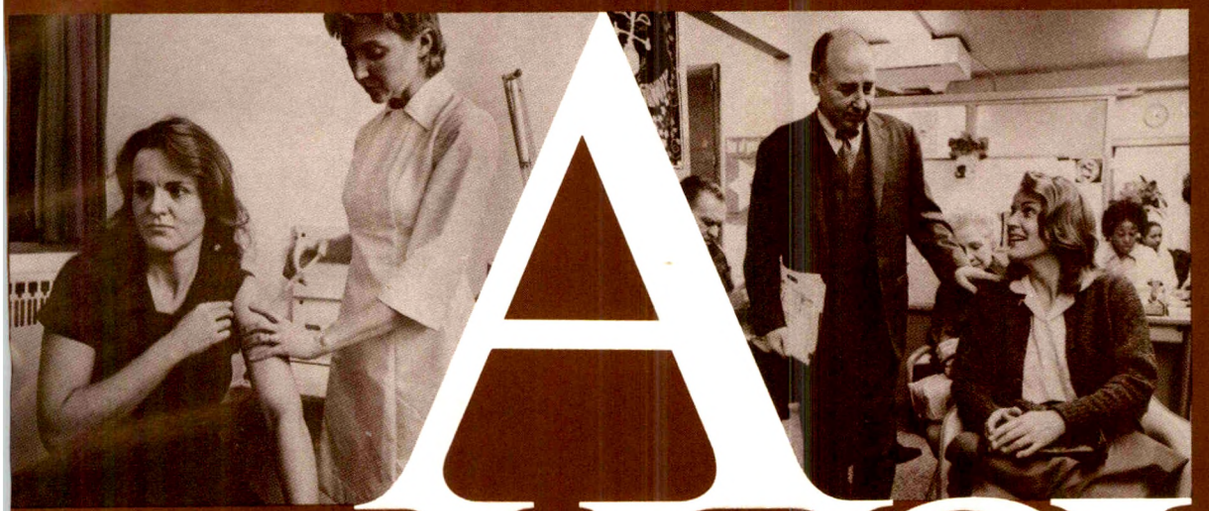
IMPLEMENTATION OF THE PROBLEM ORIENTED MEDICAL RECORD—We can also be of material assistance if you are planning a **PSRO** or a **HMO.**

Biomedimation's services are as reliable and as easy to install and maintain as your office typewriter. They are more convenient to use than a typewriter, a time-sharing terminal or a batch processing computer.

Data collection, transcription and indexing errors are dampened to the level that meets your specific requirements at data entry.

Sensitive data and information are always absolutely secure. Retrieval and display of data and information, visually and/or in hard copy, is virtually unlimited. All source entries are instantly available, always.

At the conclusion of a trial use period, we believe you will agree that Biomedimation's services satisfy your needs at less true cost . . . at any level of activity, under any time constraints, at any level of confidentiality, and to a greater degree of satisfaction at every level of human involvement.



Biomedimation will establish these facts to your satisfaction by providing you with a trial use period.

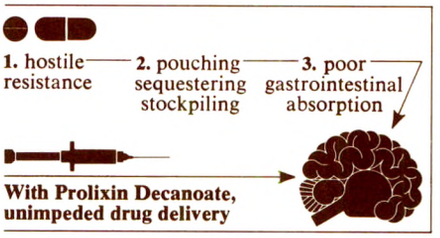
For schizophrenic patients...

A way out:

...that helps keep them out

Controlled Drug Delivery

with new



PROLIXIN® DECANOATE
(FLUPHENAZINE DECANOATE INJECTION)

Puts control of the schizophrenic in your hands with injections 1 to 3 weeks apart or longer with an average duration of effect of about 2 weeks

Controlled drug delivery – a revolution in patient management

PROLIXIN® DECANOATE (Fluphenazine Decanoate Injection) HELPS ASSURE EFFECTIVE, UNHINDERED MEDICATION

Controlled drug delivery is *physician*-controlled delivery, an effective prophylactic maneuver against disruption of therapy—one of the most common causes of psychotic relapse. Is the patient taking his medication? You know because you administer it or direct others to. Once administered, therapy cannot be altered by the patient, by his family, or by anyone else.

In most patients, symptomatology is controlled by Prolixin Decanoate for periods of two weeks with a single injection. Sequestered medication and similar problems associated with oral therapy are not encountered. Nor does the patient risk drug loss through severe diarrhea or poor gastrointestinal absorption. Prolixin Decanoate keeps the patient medicated...helps make him more amenable to the entire treatment program and improves his chances for rehabilitation and discharge.

The outpatient is vulnerable to the dictates of his own poor judgment. Deluded by a sense of well-being, he may question the need for medication. Family and friends often give him misleading advice. Oral therapy in such a patient encourages missed doses. Medication with Prolixin Decanoate (Fluphenazine Decanoate Injection) helps assure drug delivery when required and in the dosage prescribed. It helps keep the outpatient out.

FOUR REASONS FOR READMISSION...

For brief summary, see last page of this presentation.

'ROLIXIN® DECANOATE
Fluphenazine Decanoate Injection)
.SSURES ECONOMIC DRUG
)ELIVERY...LESS FREQUENT
)OSING THAN WITH ORAL
'HERAPY

Controlled drug delivery brings cost
f therapy down with less hospitaliza-
on, less nursing time, less frequent
osing. Low annual dosage means less
ost for the hospital, for the patient's
mily, and for the community. It
eans a minimum of drug holidays to
void long-term complications, with
eir confusing schedules for patient
id family.

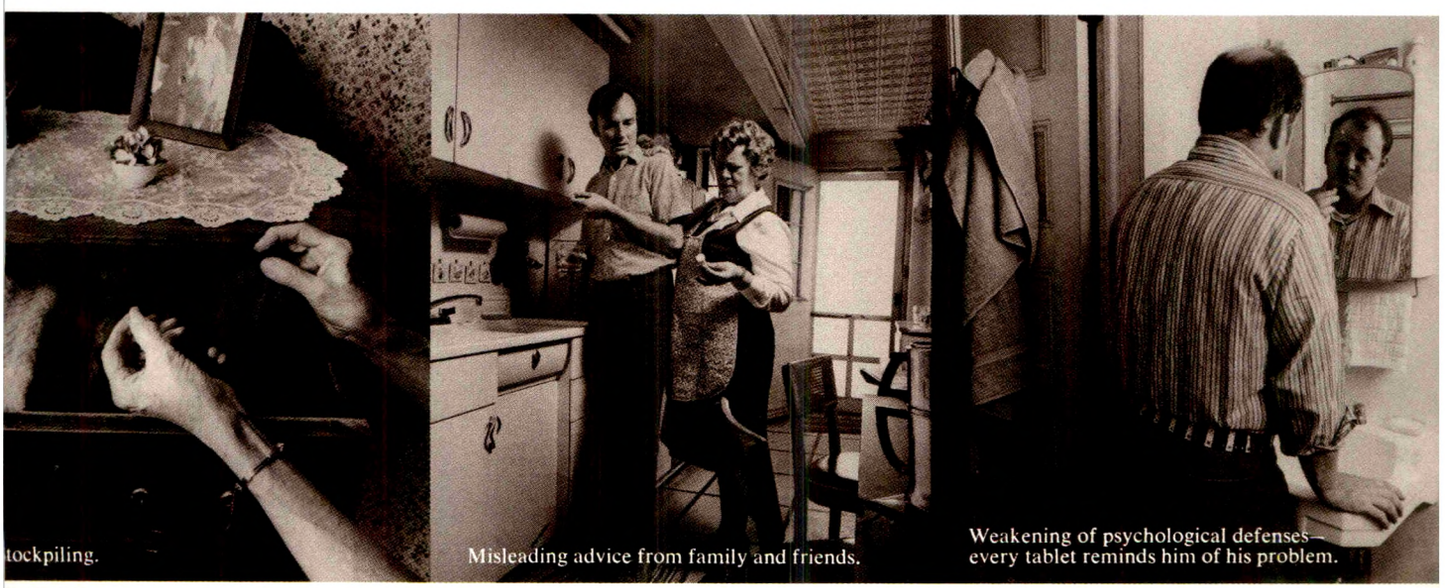
'ontrolled drug delivery—
revolution in the treatment of the
:hizophrenic patient

ROLIXIN® DECANOATE
Fluphenazine Decanoate Injection)
ELPS ENHANCE LIKELIHOOD
F DISCHARGE

Optimally, the mental hospital
ould be a rehabilitating bridge be-
veen life before and life after custo-
ial care. Prolixin Decanoate often
iortens that bridge because getting the
patient out is frequently a matter of
eeping him medicated. And 1 injec-
on of Prolixin Decanoate means ap-
roximately 2 weeks of symptom
ontrol. The importance of control by
e physician with this injectable can
e seen in the fact that about 1 out of
very 5 inpatients does not take his tab-
ts even when they are administered by nursing staff. With controlled drug delivery, lost or hidden doses are not a problem.

In one study,[1] 24 chronic long-term hospital patients were treated with Prolixin Decanoate in dosages of 12.5 mg. to 75 mg. given every 7 days to 3 weeks. Most of the patients received 25 to 50 mg. per injection. Of these, 13 were discharged after 6 months of treatment, 4 were considered dischargeable, and 7 did not improve. In 12 of the 24 patients who previously had been on different psychotropic drugs for periods of 4 to 96 weeks, improvement with Prolixin Decanoate (Fluphenazine Decanoate Injection) was observed in affect, volition, and higher mental functions. Dischargeability in these patients "may also have been enhanced because the staff, the patient, and the family were assured of an adequate and regular medication intake."[1]

Controlled drug delivery—
a revolution in the care of the outpatient



PROLIXIN® DECANOATE
(Fluphenazine Decanoate Injection)
PROMOTES CONTINUITY OF MEDICATION WITH DIMINISHED LIKELIHOOD OF RELAPSE COMPARED WITH ORAL THERAPY

Success in rehabilitative areas like employment and social acceptance depends in large measure on adequate and continuing phenothiazine intake; success in family adjustment no less so. Short-acting medication is not the best path to such success. According to one report,[2] "approximately 50% of all discharged psychotic patients fail to take even the first dose of their outpatient medication." And McClellan and Cowan[3] state that a substantial number of patients taking antipsychotic drugs do so in amounts significantly less than those prescribed. Even once-daily administration does not solve the problem of poor home supervision or the patient's lack of insight into his condition.

Controlled drug delivery with Prolixin Decanoate (Fluphenazine Decanoate Injection) is an efficient route to continuity of medication, and therefore to long-term remission. For one thing there is less strain on the patient's often tenuous adjustment to family living. Since family members are not responsible for supervising the patient's medical needs, they tend to be more accepting, and better feeling is promoted merely because the controlled delivery regimen demonstrates that improvement is possible. Controlled drug delivery also strengthens the patient's psychological defenses. He is not reminded of his psychiatric illness by multiple daily doses.

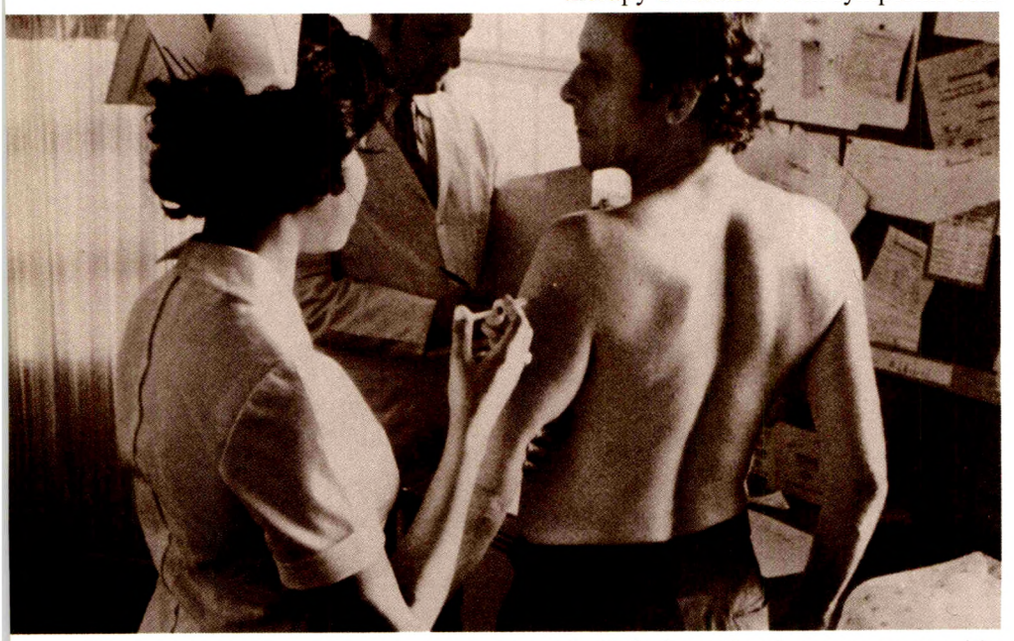
The same unique advantages of controlled drug delivery with Prolixin Decanoate that promote the discharge-

(Continued on following page)

tockpiling.

Misleading advice from family and friends.

Weakening of psychological defenses—every tablet reminds him of his problem.



OOD REASONS FOR CONTROLLED DRUG DELIVERY

(Continued from preceding page)
ability of the inpatient and help maintain him in the community are true for the patient who has never been hospitalized. It is just these advantages that will help the physician or psychiatrist keep him in the community without the need for custodial care.

Controlled drug delivery—a revolution in efficiency of administration

PROLIXIN® DECANOATE (Fluphenazine Decanoate Injection) SAVES TIME, REDUCES COST IN THE HOSPITAL, CLINIC, OFFICE

Controlled drug delivery saves time, reduces costs in the hospital. With Prolixin Decanoate there can be no palming, pouching, regurgitating. With Prolixin Decanoate resistance to therapy dwindles. With symptoms con-

trolled, the patient is more manageable, more comfortable, more amenable to the total hospital treatment program. With Prolixin Decanoate only 1 dose visit every 1 to 3 weeks with an average of about 2 weeks is required.

Controlled drug delivery saves time, reduces costs in the clinic and office.

With Prolixin Decanoate less frequen dosing. With Prolixin Decanoate (Fl phenazine Decanoate Injection) mos patients report for their injections onl once in every 2-week period.

NURSING TIME SAVED IN 14 DAYS: 30 hours, 20 minutes[4]	

Controlled drug delivery—a revolution in convenience of administration

PROLIXIN® DECANOATE (Fluphenazine Decanoate Injection) MAY BE DELIVERED IN EASY-TO-USE UNIMATIC® SYRINGES

Prolixin Decanoate may be give intramuscularly or subcutaneous Local tissue reactions occur only rare

A dry syringe and needle of at lea 21 gauge should be used. Use of a w needle or syringe may cause the sol tion to become cloudy. Prolixin Dec noate is available in vials of 5 cc. an in Unimatic single-dose preassemble syringes and in Unimatic cartridg needle units with a reusable-plasti holder.

N.B. Extrapyramidal reactions c cur frequently. Most often they are r versible and can usually be controlle by administration of antiparkinsonia drugs. However, in some instanc they are persistent (see Adverse R actions section of Brief Summary Patients should be forewarned an reassured.

PROLIXIN® DECANOATE

(FLUPHENAZINE DECANOATE INJECTION)

BRIEF SUMMARY

Prolixin Decanoate (Fluphenazine Decanoate Injection) provides 25 mg. fluphenazine decanoate per cc. in a sesame oil vehicle with 1.2% (w/v) benzyl alcohol as a preservative.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia, liver damage or renal insufficiency, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

Not intended for use in children under 12.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Physicians should be alert to the possibility that severe adverse reactions may occur which require immediate medical attention. Potentiation of effects of alcohol may occur. Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administered during pregnancy.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anti-cholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine decanoate cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with ulcer disease history since aggravation of peptic ulcer has occurred; in patients with history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

Fluphenazine decanoate should be administered under the direction of a physician experienced in the clinical use of psychotropic drugs. Periodic checking of hepatic and renal functions and blood picture should be done. Renal function of patients on long-term therapy should be monitored; if BUN becomes abnormal, treatment should be discontinued. "Silent pneumonias" are possible.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. These include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, and hyperreflexia; most often these are reversible, but they may be persistent. One can expect a higher incidence of such reactions with fluphenazine decanoate than with less potent piperazine derivatives or straight-chain phenothiazines. The incidence and severity will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of anti-parkinsonian drugs such as benztropine mesylate or intravenous Caffeine and Sodium Benzoate Injection U.S.P., and by subsequent reduction in dosage. A persistent and sometimes irreversible pseudo-parkinsonian syndrome may develop with chronic administration of phenothiazine compounds. Rhythmic, stereotyped dyskinetic involuntary movements, particularly of the face, mouth, tongue and jaw occur, and may be accompanied by choreiform movements of the limbs. The symptoms persist after drug withdrawal. Anti-parkinsonian agents are seldom of benefit. The risk appears to be greatest in elderly females with organic brain damage receiving large and prolonged doses. Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams and reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may have to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection U.S.P. is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.

Hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines. Local tissue reactions occur only rarely with injections of fluphenazine decanoate.

For full prescribing information, consult package insert.

Supply: 1 cc. Unimatic® single dose preassembled syringes and cartridge-needle units, and 5 cc. vials.

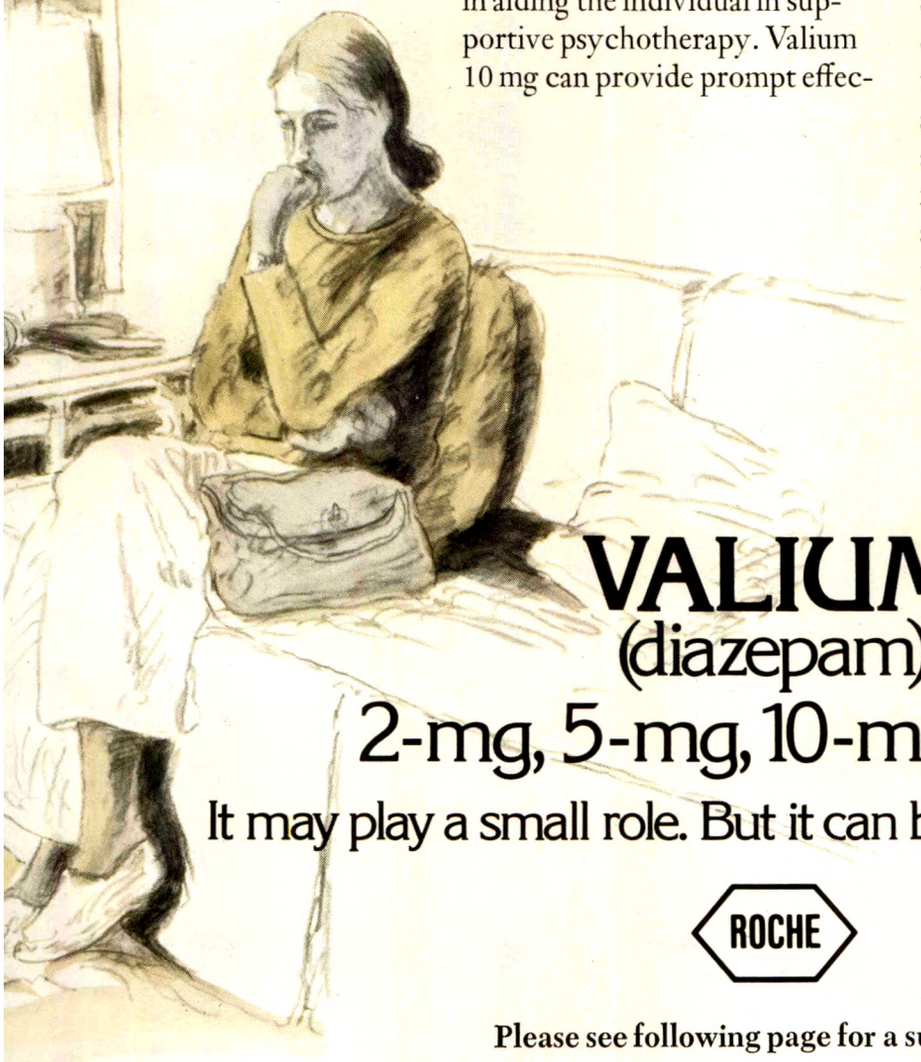
VALIUM®
(diazepam)
IN THE CONTEXT OF SUPPORTIVE PSYCHOTHERAPY

To help reduce psychic tension and anxiety

Symptoms of anxiety and tension often appear when the psychiatric patient's self-esteem, individual integrity and security are threatened. The patient may feel out of control, incompetent and insecure when the ego is unable to manage stressful stimuli. If a state of tension prevents the patient from handling problems with calm and logic, the adaptive functioning of the ego may be further impaired. When symptoms of anxiety and tension become excessive, the patient's distress may be incapacitating.

In supportive psychotherapy where the goal is to brace the ego and restore its adaptive functioning, acute anxiety and tension must be modified. Your sympathetic recognition of the patient's difficulty in relating disturbing experiences or symptoms fosters a sense of understanding and emotional closeness. Your reassurance, empathy and hope help dissipate feelings of isolation and attenuate anxiety. If these supportive measures are not enough to reduce anxiety and



psychic tension to manageable levels, consider Valium (diazepam). Valium, used adjunctively with your supportive measures, can help stabilize your patient by minimizing these excessive symptoms.

Whether you use supportive therapy alone or in conjunction with other forms of therapy, you provide the patient with an auxiliary ego which shares the responsibility of *coping*. Your genuine reassurance and encouragement give the patient confidence and reduce undue stress from external pressures by fortifying ego defenses. If symptoms of excessive anxiety and tension are reduced, the patient can develop a more independent attitude and assume control of the situation. In your treatment of the patient whose symptoms must be modified immediately, the antianxiety and tension-reducing qualities of Valium (diazepam) can be helpful.

The adjunctive role of Valium may be significant in aiding the individual in supportive psychotherapy. Valium 10 mg can provide prompt effective action in minimizing or eliminating excessive psychic tension and anxiety. Once the symptoms are reduced to a manageable level, Valium (diazepam) may be continued as needed with 2 mg or 5 mg t.i.d. or q.i.d. or discontinued entirely.

Valium is generally well tolerated in the usual dosage range. The most frequently reported side effects have been drowsiness, fatigue and ataxia. Your patients should be cautioned against engaging in hazardous occupations or driving during Valium therapy.

When impaired ego function is accompanied by excessive anxiety and psychic tension, the patient needs your supportive help. If the symptoms are incapacitating and must immediately be reduced, consider Valium as an adjunctive psychotherapeutic aid.

VALIUM®
(diazepam)
2-mg, 5-mg, 10-mg tablets

It may play a small role. But it can be an important one.

ROCHE

Please see following page for a summary of product information.

VALIUM®
(diazepam)
2-mg, 5-mg, 10-mg tablets

In the context of supportive psychotherapy, helps reduce psychic tension and anxiety.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states, somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology, spasticity caused by upper motor neuron disorders, athetosis, stiff-man syndrome, convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, lactation or women of childbearing age, weigh potential benefit against possible hazard.

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d. alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg; bottles of 100 and 500. All strengths also available in Tel-E-Dose® packages of 1000.

UNIVERSITY OF BRITISH COLUMBIA

Department of Psychiatry

Applications are being accepted for admission at all levels, to a 4 year Residency Training Program in Psychiatry, beginning July 1, 1973 at the University of British Columbia.

Teaching facilities are varied and afford an integrated program with a wide range of clinical experiences leading to the specialty qualification in psychiatry.

Salaries range from $6,780 to $10,680, with government bursaries available to a number of residents.

Apply to: Robert Krell, M.D.
Director of Postgraduate Training,

Hospital & Community Psychiatry

September 17–20, 1973
Americana Hotel, Miami Beach, Florida

THEME: "A Quarter of a Century: Where are We Now?"

Faculty and participants will critically examine and discuss the past, present and future of delivery of mental health systems in three categories:

Economics of Mental Health Care

Legislative Aspects of the Care of the Mentally Ill

Biological, Psycho-social and Social Systems Approaches to Mental Health Care

PSYCHIATRIC RESIDENCY AND INTERNSHIP PROGRAM

Psychiatry training at Saint Elizabeths Hospital is intent on developing a dynamic program based on the principles and practice of hospital and community psychiatry: one which brings to the resident a very challenging experience with an inner-city population whose mental health and social problems are multiple and complex. The program currently has positions available for the academic year beginning July 1973.

The large R-6 Internship Program consists of four months of medical training, and eight months of inpatient psychiatry providing experience with both outpatients and in the screening and admission of acute patients. If followed by two years of psychiatric residency, the trainee is enabled to complete his residency requirements in Psychiatry.

The first year residency level can be entered by those who have completed a straight, rotating or mixed internship and is conducted at the community mental health center at Saint Elizabeths Hospital. Primarily, the resident is assigned to inpatient psychiatry with a small group of patients on the Training Unit under the direct supervision of the psychiatric residency training faculty. Experience is also provided with outpatients and acute admissions work.

The second year is focused on intensive psychotherapy of outpatients. The resident is involved in individual psychotherapy, group therapy and family therapy. In addition, he treats selected children and adolescents.

The third year of training consists of the resident's choice of elective experiences from the many clinical and research opportunities available at historic Saint Elizabeths Hospital.

STIPENDS: R-6 Interns	$10,848	Second-Year Residents	$12,757
First-Year Residents	$11,882	Third-Year Residents	$13,311

An Equal Opportunity Employer

CANADA
SASKATCHEWAN DEPARTMENT OF PUBLIC HEALTH
PSYCHIATRIC SERVICES BRANCH
requires for
YORKTON PSYCHIATRIC CENTRE
REGIONAL DIRECTOR III

SALARY — $27,912 to $35,616 for D.P.M. or American Boards and full license.
$30,768 to $39,264 for Certification (C) and full license.

The Yorkton Psychiatric Centre was established in 1964 as the Province's first small regional psychiatric hospital. It is an attractive 60-bed unit which provides services to a region with a population of about 100,000. Professional staff includes psychiatrists, social workers, psychologists and psychiatric nurses.

DUTIES — To assume responsibility for overall direction of a comprehensive service program. Important aspects of this responsibility are integration of the contribution of the various mental health disciplines, and establishment of an effective working relationship with the medical profession, public and private agencies, and the general public.

QUALIFICATIONS — In addition to the medical and psychiatric qualifications indicated under salary, several years experience in the directing of community psychiatric programs including experience at a senior administrative level.

Further particulars and application forms available by writing to: Mr. W. Munn, Psychiatric Services Branch, Provincial Health Building, Regina, Saskatchewan, Canada. Completed application forms should be returned to Mr. W. Munn. Please quote competition #cc6425.

Suspicious and hostile?...Or accessible?

While psychotic symptoms remain acute, the barrier between you and the overly suspicious, hostile patient may be insurmountable. Prompt intervention with HALDOL (haloperidol) often makes it possible for you to reach... relate...rehabilitate.

And rapport with such patients is further enhanced because HALDOL usually leave patients alert and relatively non-sedated.

accessibility often begins with

HALDOL® (haloperidol)

For information relating to Indications, Contraindications, Warnings, Precautions and Adverse Reactions, please turn page.

Haldol®
(HALOPERIDOL)

a first choice for prompt rapport

A Dosage Form for Every Need:

4 tablet strengths for convenience in individualizing dosage: ½ mg., 1 mg., 2 mg. and 5 mg.

An undetectable, tasteless Liquid Concentrate for the patient unable or unwilling to swallow tablets: 2 mg. per cc.

A rapid-acting Injection for psychiatric emergencies: 5 mg. per cc., with 0.5 mg. methylparaben and 0.05 mg. propylparaben per cc., and lactic acid for pH adjustment to 3.4±0.2.

Summary of Directions for Use

Indications: For the treatment of such symptoms as moderate to severe agitation, anxiety and tension, assaultiveness, delusions, hallucinations, hostility, and hyperactivity when they are manifestations of psychosis including schizophrenia, the manic type of manic depressive illness, or psychotic reactions associated with organic brain syndromes or mental retardation. For the control of tics and vocal utterances of Gilles de la Tourette's Syndrome.

Contraindications: HALDOL (haloperidol) is contraindicated in patients who are severely depressed, comatose, have CNS depression due to alcohol or other centrally-acting depressants, have Parkinson's disease or are hypersensitive to this drug.

Warnings: ***Usage in Pregnancy***—Safe use of HALDOL (haloperidol) in pregnancy and lactation has not been established; therefore, its use in pregnancy, in nursing mothers, or in women of childbearing potential requires that the possible benefits of the drug be weighed against the potential hazards. A case of phocomelia in an infant whose mother received haloperidol along with a number of other medications during the first trimester of pregnancy has been reported (a causal relationship was not established in this case). Animals receiving 2 to 20 times the maximum human dose of HALDOL orally and/or parenterally showed increased incidence of resorption, reduced fertility, delayed delivery, dose-related pup mortality (presumably due to lack of maternal care reflecting CNS depression).

Usage in Children—Safety and effectiveness in children have not been established; therefore, this drug is not recommended for use in the pediatric age group.

General—Cases of bronchopneumonia, some fatal, have followed the use of major tranquilizers, including haloperidol. It has been postulated that lethargy and decreased sensation of thirst may lead to dehydration, hemoconcentration and reduced pulmonary ventilation. If these signs and symptoms appear, especially in the elderly, the physician should institute remedial therapy promptly. Although not reported with HALDOL (haloperidol), decreased serum cholesterol and/or cutaneous and ocular changes have been reported in patients receiving chemically-related drugs. HALDOL may impair the mental and/or physical abilities required for the performance of hazardous tasks such as operating machinery or driving a motor vehicle. The ambulatory patient should be warned accordingly. The use of alcohol should be avoided due to possible additive effects and hypotension.

Precautions: HALDOL (haloperidol) should be administered cautiously to patients: (1)—with severe cardiovascular disorders, because of the possibility of transient hypotension and/or precipitation of anginal pain. Should hypotension occur and a vasopressor be required, *epinephrine should not be used* since HALDOL may block its vasopressor activity and paradoxical further lowering of blood pressure may occur. (2)—receiving anticonvulsant medication, because HALDOL may lower the convulsive threshold, although it will *not* increase the effects of anticonvulsant medication. Adequate anticonvulsant therapy should be maintained concomitantly. (3)—with known allergies, or with a history of allergic reactions to drugs. (4)—receiving anticoagulants, since an isolated instance of interference occurred with the effects of one anticoagulant (phenindione).

If concomitant anti-Parkinson medication is required, it may have to be continued after haloperidol is discontinued because of the difference in excretion rates. If both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including anti-Parkinson agents, are administered concomitantly with HALDOL. When HALDOL is used to control mania in cyclic disorders there may be a rapid mood swing to depression.

Adverse Reactions: ***CNS Effects:*** *Extrapyramidal Reactions*—Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which usually were mild to moderately severe and reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally extrapyramidal symptoms are dose related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Administration of anti-Parkinson drugs may be required for control of such reactions. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases. *Other CNS Effects*—Insomnia, restlessness, anxiety, euphoria, agitation, drowsiness, depression, lethargy, headache, confusion, vertigo, grand mal seizures, and exacerbation of psychotic symptoms including hallucinations. ***Cardiovascular Effects:*** Tachycardia and hypotension. ***Hematologic Effects:*** Reports have appeared of mild and usually transient leukopenia and leukocytosis, minimal decreases in red blood cell counts, anemia, or a tendency toward lymphomonocytosis. Agranulocytosis has rarely been reported and then only in association with other medication. ***Liver Effects:*** Impaired liver function and/or jaundice have been reported, although a causal relationship has not been established. ***Dermatologic Reactions:*** Maculopapular and acneiform skin reactions and isolated cases of photosensitivity and loss of hair. ***Endocrine Disorders:*** Lactation, breast engorgement, mastalgia, menstrual irregularities, gynecomastia, impotence, increased libido, hyperglycemia and hypoglycemia. ***Gastrointestinal Effects:*** Anorexia, constipation, diarrhea, hypersalivation, dyspepsia, nausea and vomiting. ***Autonomic Reactions:*** Dry mouth, blurred vision, urinary retention and diaphoresis. ***Respiratory Effects:*** Laryngospasm, bronchospasm and increased depth of respiration.

Complete dosage information available in insert which accompanies each package (or on request).

The use of the injectable form is intended for the acutely agitated psychotic patient with moderately severe to very severe symptoms.

IMPORTANT: Full directions for use should be read before HALDOL (haloperidol) is administered or prescribed. 11/72

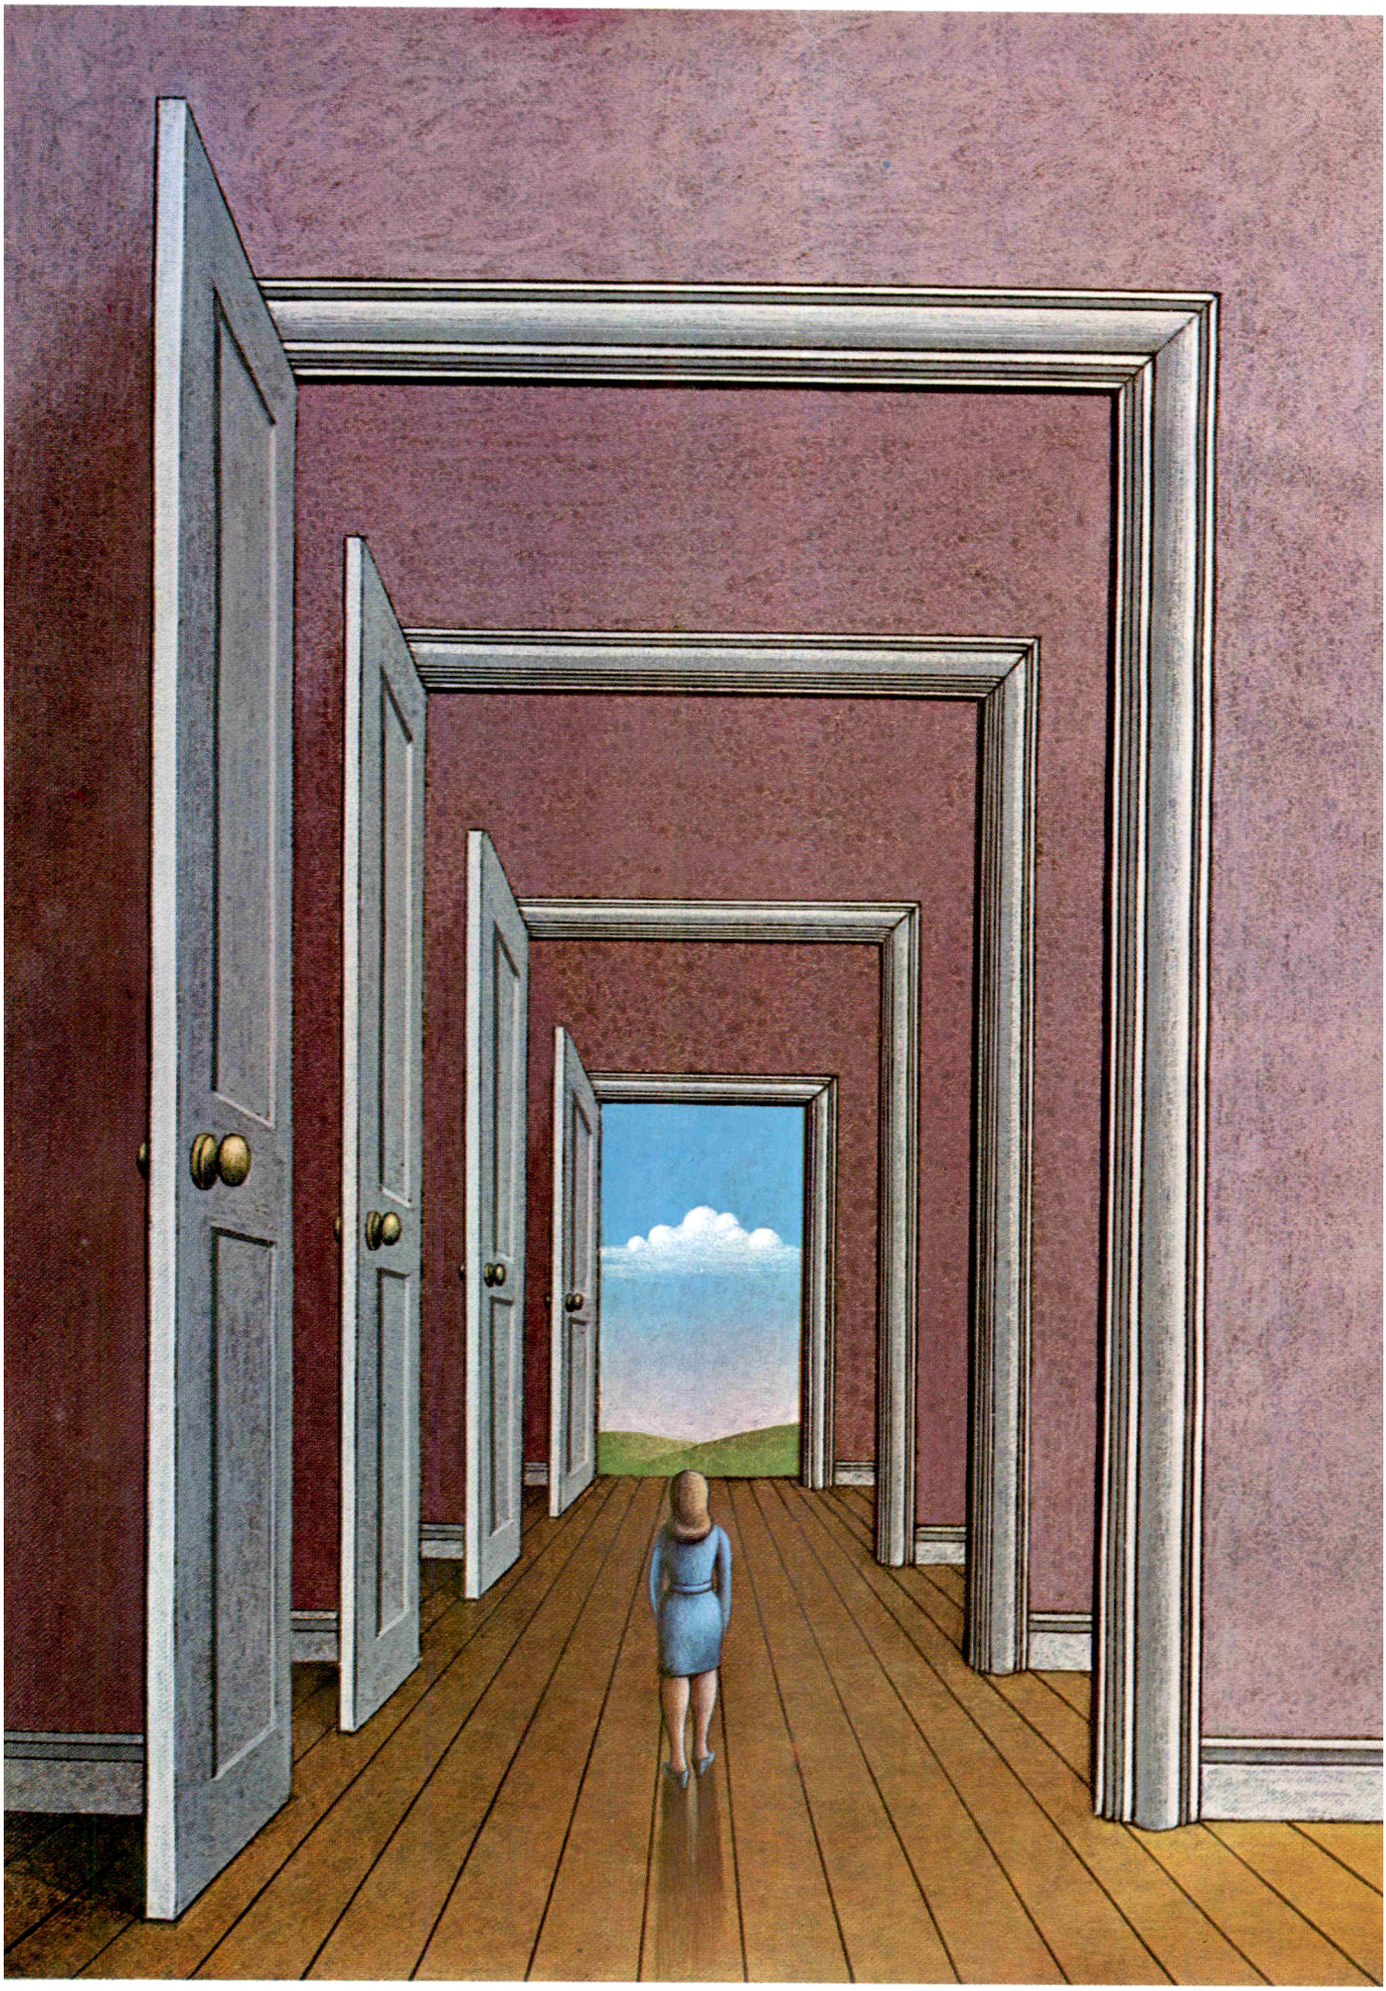
BALDPATE, INC.

A PRIVATE PSYCHIATRIC HOSPITAL
GEORGETOWN, MASS. 01830
(617) 352-2131

Located 30 miles north of Boston on 130 acres, set among peaceful meadows bordering a quiet lake and wooded hill, Baldpate presents a relaxing atmosphere to the problem-beset patient.

Baldpate is an active treatment hospital for psychoses, neuroses, alcoholism, and drug addiction.



Psychotherapy, somatic therapy, milieu therapy, and pharmacotherapy are available from qualified physicians. There is also occupational and recreational therapy under the direction of trained therapists.

Single rooms with and without bath, shared accommodations, and cottages are available.
Most major health insurance plans acceptable.

PATRICK J. QUIRKE, M.D.
Medical Director

A HEAD START FOR THE CLINICALLY DEPRESSED PATIENT.

All tricyclic antidepressants take from one to four weeks before optimal antidepressant effect is seen.

Sinequan (doxepin HCl)—the newest tricyclic antidepressant—is no exception.

But, in that waiting period, Sinequan offers the clinically depressed patient both:

prompt sedative activity to begin relieving the sleep disturbances often characteristic of depression, and

marked antianxiety activity to help relieve the apprehension, tension, worry and fear that usually accompany depression.

Further, the incidence of cardiovascular side effects with Sinequan is relatively low. Tachycardia and hypotension are infrequent. (Drowsiness is the most common side effect.) And Sinequan, unlike other tricyclic antidepressants, does not generally affect the activity of guanethidine and similarly acting compounds at usual clinical doses.

Prompt sedative activity. Marked antianxiety activity. Low incidence of cardiovascular side effects.

It's a head start for the clinically depressed patient.

THE NEWEST TRICYCLIC ANTIDEPRESSANT— WITH DIFFERENCES YOU CAN SEE.

Sinequan®
DOXEPIN HCl
25-mg. and 50-mg. capsules

©1973, PFIZER INC.

Sinequan®
DOXEPIN HCl
25-mg. and 50-mg. capsules

THE NEWEST TRICYCLIC ANTIDEPRESSANT—WITH DIFFERENCES YOU CAN SEE.

BRIEF SUMMARY

Sinequan® (doxepin HCl) **Capsules**

Contraindications. Sinequan (doxepin HCl) is contraindicated in individuals who have shown hypersensitivity to the drug.

Sinequan (doxepin HCl) is contraindicated in patients with glaucoma or a tendency to urinary retention.

Warnings. *Usage in Pregnancy:* Sinequan (doxepin HCl) has not been studied in the pregnant patient. It should not be used in pregnant women unless, in the judgment of the physician, it is essential for the welfare of the patient, although animal reproductive studies have not resulted in any teratogenic effects.

Usage in Children: The use of Sinequan (doxepin HCl) in children under 12 years of age is not recommended, because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with Sinequan (doxepin HCl). The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered, and the dosage involved.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug.

Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy.

Although Sinequan (doxepin HCl) has significant tranquilizing activity, the possibility of activation of psychotic symptoms should be kept in mind.

Other structurally related psychotherapeutic agents (e.g., iminodibenzyls and dibenzocycloheptenes) are capable of blocking the effects of guanethidine and similarly acting compounds in both the animal and man. Sinequan (doxepin HCl), however, does not show this effect in animals. At the usual clinical dosage, 75 to 150 mg. per day, Sinequan (doxepin HCl) can be given concomitantly with guanethidine and related compounds without blocking the antihypertensive effect. At doses of 300 mg. per day or above, Sinequan (doxepin HCl) does exert a significant blocking effect. In addition, Sinequan (doxepin HCl) was similar to the other structurally related psychotherapeutic agents as regards its ability to potentiate norepinephrine response in the animal. However, in the human this effect was not seen. This is in agreement with the low incidence of the side effect of tachycardia seen clinically.

Adverse Reactions. *Anticholinergic Effects:* Dry mouth, blurred vision, and constipation have been reported. They are usually mild, and often subside with continued therapy or reduction of dose.

Central Nervous System Effects: Drowsiness has been observed. This usually occurs early in the course of treatment, and tends to disappear as therapy is continued.

Cardiovascular Effects: Tachycardia and hypotension have been reported infrequently.

Other infrequently reported side effects include extrapyramidal symptoms, gastrointestinal reactions, secretory effects such as increased sweating, weakness, dizziness, fatigue, weight gain, edema, paresthesias, flushing, chills, tinnitus, photophobia, decreased libido, rash, and pruritus.

Dosage. For most patients with illness of mild to moderate severity, a starting dose of 25 mg. t.i.d. is recommended. Dosage may subsequently be increased or decreased at appropriate intervals and according to individual response. The usual optimum dose range is 75 mg./day to 150 mg./day.

In more severely ill patients an initial dose of 50 mg. t.i.d. may be required with subsequent gradual increase to 300 mg./day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding a dose of 300 mg./day.

In patients with very mild symptomatology or emotional symptoms accompanying organic disease, lower doses may suffice. Some of these patients have been controlled on doses as low as 25-50 mg./day.

Although optimal antidepressant response may not be evident for two to three weeks, antianxiety activity is rapidly apparent.

Supply. Sinequan (doxepin HCl) is available as capsules containing doxepin HCl equivalent to 10 mg., 25 mg., and 50 mg. of doxepin in bottles of 100 and 1000.

Focus on rapidity of response...
Antidepressant effect often apparent within 3 to 5 days
Mild accompanying anxiety—as well as psychosomatic complaints and other depressive symptoms—usually disappear as the depression lifts.
Optimal response in most patients with 50 mg. t.i.d. Adolescents and elderly patients often do well on lower dosage.
Pertofrane®
(desipramine hydrochloride NF)
an antidepressant that brings things into focus—promptly
USV
PHARMACEUTICALS

Pertofrane®
(desipramine hydrochloride)

Indication: For relief of mental depression.
Contraindications: Do not use MAO inhibitors concomitantly or within 2 weeks of the use of this drug. Hyperpyretic crises c severe convulsive seizures may occur with such combination potentiation of adverse reactions can be serious or even fatal. When substituting Pertofrane in patients receiving an MAO inhibitor, allow an interval of at least 14 days. Initial dosage in such patients should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated following recent myocardial infarction and in patients with a known hypersensitivity to tricyclic antidepressants. **Warnings** Activation of psychosis may occasionally be observed in schizophrenic patients. Due to atropine-like effects and sympathomimetic potentiation, use only with the greatest care in patients with narrow-angle glaucoma or urethral or ureteral spasm. Do not use in patients with the following conditions unless the need outweighs the risk: severe coronary heart disease with EKG abnormalities, progressive heart failure, angina pectoris, paroxysmal tachycardia and active seizure disorder (may lower seizure threshold). This drug may block the action of the antihypertensive, guanethidine, and related adrenergic neuron-blocking agents. Hypertensive episodes have been observed during surgery. The concurrent use of other central nervous system drugs or alcohol may potentiate adverse effects. Since many such drugs may be used during surgery, desipramine should be discontinued prior to elective procedures. Caution patients on the possibility of impaired ability to operate a motor vehicle or dangerous machinery. Do not use in women who are or may become pregnant, or in children under 12 years of age, unless the clinical situation warrants the potential risk. Because of increased sensitivity to the drug, use lower than normal dosage in adolescent and geriatric patients. **Precautions:** Potentially suicidal patients require careful supervision and protective measures during therapy. Prescriptions should be limited to small quantities. Discontinuation of the drug may be necessary in the presence of increased agitation and anxiety shifting to hypomanic or manic excitement. Atropine-like effects may be more pronounced (e.g. paralytic ileus) in susceptible patients and in those receiving anticholinergic drugs (including antiparkinsonism agents). Prescribe cautiously in hyperthyroid patients and in those receiving thyroid medications; transient cardiac arrhythmias have occurred in rare instances. Periodic blood and liver studies should supplement careful clinical observations in all patients undergoing extended courses of therapy. **Adverse Reactions:** The following have been reported: *Nervous System:* dizziness, drowsiness, insomnia, headache, disturbed visual accommodation, tremor, unsteadiness, tinnitus, paresthesias, changes in EEG pattern, epileptiform seizures, mild extrapyramidal activity, falling and neuromuscular incoordination. A confusional state (with such symptoms as hallucinations and disorientation), particularly in older patients and at higher dosage, may require discontinuation of the drug. *Gastrointestinal Tract:* anorexia, dryness of the mouth, nausea, epigastric distress, constipation and diarrhea. *Skin:* skin rashes (including photosensitization), perspiration and flushing sensations. *Liver:* rare cases of transient jaundice (apparently of an obstructive nature) and liver damage. If jaundice or abnormalities in liver function tests occur, discontinue the drug and investigate. *Blood Elements:* bone-marrow depression, agranulocytosis, thrombocytopenia and purpura. If these occur, discontinue the drug. Transient eosinophilia has been observed. *Cardiovascular System:* orthostatic hypotension and tachycardia. Carefully supervise patients requiring concomitant vasodilating therapy, particularly during initial phases. *Genitourinary System:* urinary frequency or retention and impotence. *Endocrine System:* occasional hormonal effects, including gynecomastia, galactorrhea and breast enlargement, and decreased libido and estrogenic effect. *Sensitivity:* urticaria and rare instances of drug fever and cross-sensitivity with imipramine.
Dosage: All patients except geriatric and adolescent: 50 mg t.i.d. (150 mg. daily). Dosage may be increased up to 200 mg daily. Geriatric and adolescent patients should usually be started with lower dosage (25 to 50 mg. daily) and may not tolerate higher doses. Dosage may be increased up to 100 mg daily. Lower maintenance dosages should be continued for at least 2 months after obtaining a satisfactory response. Mild anxiety and agitation which may accompany depression usually remit as the depression responds. Occasionally, however, a sedative or tranquilizer may be indicated. **How Supplied:** 25 mg. capsules (pink) and 50 mg. capsules (maroon and pink), bottles of 100 and 1000; single-dose blister packs, boxes of 500.

USV Pharmaceutical Corp., Tuckahoe, N.Y. 10707

Monday's child is fair of face,
Tuesday's child is full of grace,
Wednesday's child is full of woe...

—first three lines of anonymous nursery rhyme

Managing Wednesday's Child... the child with MBD

Wednesday's child is full of woe"
It need not be this way for the MBD child.
He can learn and adjust if given a helping hand.

Without help, the MBD child may be a slow reader, can find writing difficult, and arithmetic hard to grasp. He may be excitable, and his actions can be disruptive. The result can seriously hamper his educational and social development.

But, properly diagnosed and treated, MBD – Minimal Brain Dysfunction – can be brought under control so that the afflicted child can develop normally.

And Ritalin can play an important part in the total rehabilitation program of the MBD child, which includes remedial measures at home and at school. It's currently the drug of choice in many MBD situations.[1]

Ritalin is well tolerated. It can help control the excessive motor activity of the MBD child and ameliorate behavioral and learning problems.

Of course, Ritalin is not indicated for childhood personality and behavioral disorders not associated with MBD.

(methylphenidate hydrochloride)

TABLETS

INDICATION

Minimal Brain Dysfunction in Children—as adjunctive therapy to other remedial measures (psychological, educational, social)

Special Diagnostic Considerations

Specific etiology of Minimal Brain Dysfunction (MBD) is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.

The characteristic signs most often observed are chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate to severe hyperactivity; specific learning disabilities; perceptual motor impairment; minor neurological signs and abnormal EEG. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these signs.

Drug treatment is not indicated for all children with MBD. Appropriate educational placement is essential and psychological or social intervention may be necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.

CONTRAINDICATIONS

Marked anxiety, tension, and agitation, since Ritalin may aggravate these symptoms. Also contraindicated in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS

Ritalin is not recommended for children under six years, since safety and efficacy in this age group have not been established.

Since sufficient data on safety and efficacy of long-term use of Ritalin in children with minimal brain dysfunction are not yet available, those requiring long-term therapy should be carefully monitored.

Ritalin should not be used for severe depression of either exogenous or endogenous origin or for the prevention of normal fatigue states.

Ritalin may lower the convulsive threshold in patients with or without prior seizures; with or without prior EEG abnormalities, even in absence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. If seizures occur, Ritalin should be discontinued.

Use cautiously in patients with hypertension.

Drug Interactions

Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors. Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy

Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence

Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.

Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS

Patients with an element of agitation may react adversely; discontinue therapy if necessary.

Periodic CBC and platelet counts are advised during prolonged therapy.

ADVERSE REACTIONS

Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include: hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, and erythema multiforme with histopathological findings of necrotizing vasculitis); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmias; abdominal pain; weight loss during prolonged therapy. In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently. Toxic psychosis has been reported.

DOSAGE AND ADMINISTRATION

Children with Minimal Brain Dysfunction (6 years and over)

Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.

If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.

Ritalin should be periodically discontinued to assess the child's condition. Improvement may be sustained when the drug is either temporarily or permanently discontinued.

Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED

Tablets, 20 mg (peach, scored); bottles of 100 and 1000.
Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Strip Dispensers of 100.
Tablets, 5 mg (pale yellow); bottles of 100, 500, and 1000.

Consult complete product literature before prescribing.

The challenge: versatility

The stereotype image of "psychiatrist and couch" is an anachronism because today's psychiatrist is called on to diagnose and treat depression in a variety of clinical settings. And when an antidepressant medication is chosen, it must be as flexible and as adaptable as the physician prescribing it.

The psychiatrist's office still represents the setting in which the psychoanalytic process recognizes its fullest potential. Frequently, however, an antidepressant must be employed to foster a working therapeutic relationship. With effective symptomatic relief often provided by ELAVIL® (Amitriptyline HCl, MSD), depressed patients may be able to concentrate on underlying factors instead of somatic manifestations.

The general hospital today usually provides a psychiatric unit where depressed patients are treated. Here, too, the symptomatic relief ELAVIL often provides can be a valuable part of total treatment. As depressive symptoms are relieved, for example, patients may take advantage of the therapeutic activities offered and, even more important, may be discharged sooner and treated on an outpatient basis.

In the outpatient clinic, where follow-up treatment may be necessary for three months or longer, ELAVIL is highly effective in maintaining relief, especially in patients who responded well to higher doses while hospitalized. As a result, these patients may continue to function in their daily activities.

In the mental hospital, severely depressed patients present challenges for psychiatrist and staff alike. Here, the usefulness of ELAVIL is increased by the 50-mg tablet that provides the higher doses often required and by the injectable form for more rapid effect.

The community mental health center, a remarkable innovation in the field of modern psychiatry, offers a unique setting for treating patients with clinically significant depression. Here, too, ELAVIL often proves to be a true asset to the psychiatrist by providing highly effective symptomatic relief that can encourage communication, support the psychotherapeutic relationship, and accelerate the achievement of desired therapeutic goals.

in the treatment of depression

TABLETS: 10 mg, 25 mg, and 50 mg INJECTION: 10 mg per ml

ELAVIL®

(AMITRIPTYLINE HCl | MSD)

helps open many doors

For a brief summary of prescribing information, please see following page.

MSD
MERCK SHARP & DOHME

addendum

ELAVIL®
(AMITRIPTYLINE HCl | MSD)
dosage forms for differing patient needs

25 mg (yellow)

This tablet may prove useful for most outpatients, who generally do well on 25 mg three times a day. This dosage may be increased to a total of 150 mg a day. Dosage increases are made preferably in the late afternoon or at bedtime. The sedative effect may be apparent before the antidepressant effect is noted. An adequate therapeutic effect may take as long as 30 days to develop.

50 mg (beige)

The 50-mg tablet may be indicated whenever higher dosages are required, as for example when increases are necessary in the late afternoon or bedtime doses. It may also be convenient for many hospitalized patients who may need 100 mg a day initially. In these patients, dosage may be increased gradually to 200 mg a day if necessary. A small number of hospitalized patients may need as much as 300 mg a day.

10 mg (blue)

Because lower doses are generally recommended for adolescents and elderly patients, the 10-mg tablets may be most serviceable. Ten mg three times a day with 20 mg at bedtime may be satisfactory in adolescent and elderly patients who do not tolerate higher dosages.

INJECTION
10 mg per ml

For patients unable or unwilling to take tablets, the injectable form may be suitable initially. The tablets should replace the injection as soon as possible. Initial intramuscular dosage is 20 to 30 mg (2 to 3 ml) four times a day. When Injection ELAVIL is administered intramuscularly, the effects may appear more rapidly than with oral administration.

Usage in Children: In view of the lack of experience in children, this drug is not recommended at the present time for patients under 12 years of age.

Contraindications: Known hypersensitivity. Should not be given concomitantly wit a monoamine oxidase inhibitor or within at least 14 days following the discontir uance of a monoamine oxidase inhibitor since hyperpyretic crises, severe convu sions, and deaths have occurred. When used to replace a monoamine oxidase inhib itor, initiate dosage of amitriptyline HCl cautiously with gradual increase in dosag until optimum response is achieved. Not recommended during the acute recover phase following myocardial infarction or for patients under 12 years of age.

Warnings: May block the antihypertensive action of guanethidine or similarly actin compounds. Should be used with caution in patients with a history of seizures o urinary retention, or with angle-closure glaucoma or increased intraocular pressure Patients with cardiovascular disorders should be watched closely; arrhythmias sinus tachycardia, and prolongation of the conduction time have been reported particularly with high doses; myocardial infarction and stroke have been reporte with drugs of this class. Close supervision is required for hyperthyroid patients o those receiving thyroid medication. May impair mental and/or physical abilitie required for performance of hazardous tasks, such as operating machinery or driv ing a motor vehicle. Safe use during pregnancy and lactation has not been estab lished; in pregnant patients, nursing mothers, or women who may become pregnant weigh possible benefits against possible hazards to mother and child.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symp toms; manic depressive patients may experience a shift to the manic phase. Ir these circumstances, the dose of amitriptyline HCl may be reduced or a majo tranquilizer, such as perphenazine, may be administered concurrently.

When given with anticholinergic agents or sympathomimetic drugs, close supervi sion and careful adjustment of dosages are required. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains during treatment and until significant remission occurs; this type of patient should not have easy access to large quantities of the drug. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: The intravenous administration of 1–3 mg of physostigmine salicylate has been reported to reverse the symptoms of amitriptyline poisoning.

How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

Contraindications: Severe central nervous system depression, comatose states, hypersensitivity.

Warnings: Increase dosage gradually to patients participating in activities requiring complete mental alertness (e.g., driving). The safety of this drug in pregnancy has not been established; hence, it should be given only when the anticipated benefits to be derived from treatment exceed the possible risks to mother and fetus. Use in children under 12 is not recommended. Phenothiazines are capable of potentiating central nervous system depressants as well as atropine and phosphorus insecticides.

Precautions: Ocular changes (seen with other phenothiazines) have not been seen with Serentil (mesoridazine). Because of possible hypotensive reactions, caution in parenteral use is required. Reserve parenteral administration for bedfast patients or for acute ambulatory cases, and keep patient lying down for at least ½ hour after injection. Leukopenia and/or agranulocytosis have been attributed to phenothiazine therapy. Blood dyscrasia (seen with other phenothiazines) has occurred in a single case of transient granulocytopenia.

Adverse Reactions: Serentil (mesoridazine) has demonstrated a remarkably low incidence of adverse reactions when compared with other phenothiazine compounds. *Central Nervous System:* Drowsiness, Parkinson's syndrome, dizziness, weakness, tremor, restlessness, ataxia, dystonia, rigidity, slurring, akathisia, motoric reactions (opisthotonos). *Autonomic Nervous System:* Dry mouth, nausea and vomiting, fainting, stuffy nose, photophobia, constipation and blurred vision. *Endocrine System:* Inhibition of ejaculation and lactation have been noted rarely. *Skin:* Itching, rash, hypertrophic papillae of the tongue and angioneurotic edema. *Cardiovascular System:* Hypotension, tachycardia, EKG changes.

The following reactions have occurred with phenothiazines and should be considered: *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Serentil (mesoridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. There is no evidence that these changes are precursors of any significant disturbance of cardiac rhythm. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonos, oculogyric crises, tremor, muscular rigidity, and akinesia, occasionally persisting for several months or years especially in elderly patients with brain damage. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, weight gain, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia, behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea.

Dosage and Administration: ORAL: Should be adjusted to needs of the individual. Lowest effective dosage should always be used. When maximum response is achieved, dosage may be reduced gradually to maintenance level. *Schizophrenia:* For most patients, regardless of severity, starting dose of 50 mg. t.i.d. recommended. Usual optimum total daily dose range 100-400 mg. *Behavioral Problems in Mental Deficiency and Chronic Brain Syndrome:* For most patients starting dose of 25 mg. t.i.d. recommended. Usual optimum total daily dose range 75-300 mg. *Alcoholism:* For most patients usual starting dose is 25 mg. b.i.d. Usual optimum total daily dose range 50-200 mg. *Psychoneurotic Manifestations:* For most patients usual starting dose is 10 mg. t.i.d. Usual optimum total daily dose range 30-150 mg. INJECTABLE FORM: For situations in which an intramuscular form of medication is indicated. For most patients a starting dose of 25 mg. is recommended, to be repeated in 30-60 minutes if necessary. Usual optimum total daily dose range 25-200 mg.

Before prescribing, consult package circular.

THE AMERICAN JOURNAL OF PSYCHIATRY

Overview: Current Trends in Mental Health Law

BY A. LOUIS MCGARRY, M.D., AND HONORA A. KAPLAN, M.P.A., J.D.

This overview delineates trends in mental health law beginning with early law and proceeding to the present time. The authors discuss such recent mental-health-related judicial decisions and statutory changes as class actions, the right to treatment, admission statuses, classification of mentally ill and mentally retarded patients, involuntary commitment, and patient rights.

IN RECENT YEARS there has been extraordinary activity in the courts and legislatures of America relating to mental health law. A major new legal thesis is that adequate treatment for the institutionalized mentally ill and mentally retarded is a constitutional right. In particular, the class action suit, which we will discuss in greater detail later, has emerged as a mechanism with the potential for unprecedented and accelerated change in mental health systems.

Implicit and, in some cases, explicit in this activity is the requirement that the states reorder their priorities in order to provide adequate resources for the care and treatment of the mentally ill and retarded. It is ironic that such a charge should come at a time of financial austerity in the states, indeed at a time when a number of the states have been forced to cut their mental health budgets. It remains to be seen what the impact of all of this activity will be. The recent landmark case on the right to treatment in Alabama (1) has been appealed to the 5th Federal Circuit Court of Appeals. At stake here, among other important issues, are the degree of authority and the breadth of the remedies a federal court can impose on a state government.

This paper will not exhaustively examine all of the recent legal activity relating to mental health. Rather, we will be describing and analyzing what we regard as the major trends in representative states and courts and the implications of these trends. In doing so we may only succeed in grasping a tiger by the tail, since what will be described is a rapidly evolving, dynamic process subject to significant change tomorrow or, indeed, today.

This paper was written at the invitation of the Editor.

The authors are both with the Laboratory of Community Psychiatry, Harvard Medical School, 58 Fenwood Rd., Boston, Mass. 02115, where Dr. McGarry is Lecturer on Psychiatry and Ms. Kaplan is Associate in Psychiatry (Law). Dr. McGarry is also State Director of Legal Medicine, Massachusetts Department of Mental Health, Boston, Mass.

This work was supported by Public Health Service grant 6813-2 from the Center for Studies of Crime and Delinquency, National Institute of Mental Health.

HISTORICAL BACKGROUND

In earlier times the primary concern of legislation relating to mental illness was the protection and security of society. In colonial America there were laws relating only to the violent and indigent insane. The violent insane were generally treated as common criminals and incarcerated in jails so "that they do not damify others" (2, p. 80). The indigent or dependent insane were dealt with no differently than paupers. Going as far back as 1639, communities enacted repressive settlement laws that penalized paupers and vagabonds, and the dependent insane often roamed the countryside, literally without a home.

During the second half of the 18th century and during the early 19th century, when local communities began to deal with mental illness in a more organized fashion, jails and poorhouses were again used as solutions for the violent and indigent insane. There were, however, no statutes during this period that related to commitment of the mentally ill. Since only the violent or indigent were involved, commitment was easily accomplished. "A few words hastily scribbled on a chance scrap of paper . . . and the deed was done" (3, p. 62).

The early 19th century and the Age of Reason brought significant reform, albeit short-lived, to the treatment of the mentally ill. Due in large part to the ideas of Rush, Pinel, and Tuke, treatment and cure (rather than incarceration and punishment) seemed possible. The philosophy of "moral treatment" advocated the resocialization of the mentally ill individual within an institutional setting where his social and physical environment could be completely and therapeutically structured.

To carry out the precepts of moral treatment a few asylums or special institutions exclusively for the insane

were developed in a number of states.[1] In response to the warm and open therapeutic milieu in these facilities, as well as to selective admission policies, the asylums providing moral treatment achieved impressive success. This "cult of curability," coupled with the effective humanitarian crusades for better care and treatment for the insane led by Dorothea Dix, resulted in the establishment of a network of public facilities for the insane in addition to those under private auspices. However, procedures for commitment remained undefined by statute.

The assumption by the government of broad responsibility for the mentally ill, who were viewed as a distinctly separate group, represented a significant change in public policy. However, public institutions for the mentally disabled could no longer be selective in their admission policies. Within a short period of time public hospitals exceeded their bed capacities, while patient turnover was almost nonexistent. State facilities thus evolved into custodial, rather than therapeutic, entities, differing little from other kinds of custodial institutions, such as jails and poorhouses.

During this period of rapid growth of public asylums, a concern for the rights of the individual who had been committed to such a facility began to develop. This interest resulted more from public anxiety over the wrongful commitment of the sane than from a desire to protect the rights and liberty of the mentally ill. A vigorous campaign for strict commitment laws to prevent wrongful detention was led by Mrs. E.P.W. Packard, who herself had been confined in a mental hospital in Illinois for three years. Consequently, during the 1870s a number of states enacted fairly rigorous commitment laws, some of which included a jury determination of insanity. (Ironically, the jury trial resulted in more commitments of sane individuals than had ever been the case under any other procedure [4].) Legally, this period has been characterized as the "romance with the criminal law" (5). The overly legalistic approach to mental illness and civil commitment "contributed in no small degree to the stigma attached to mental disease" (3, p. 438). Because these statutes utilized the criminal-judicial model, they promoted the public's identification of civilly committed persons with criminals and thus created anxiety and isolation in the management of these patients.

Despite the advances in psychiatric knowledge and treatment that ensued in the 20th century, there was no major impetus for changing commitment laws until the middle of the century. After World War II, there was a growing conviction in the psychiatric community that the criminal law features of commitment statutes, including such concepts as notice and judicial hearings, were detrimental to the treatment of mental illness. During this period of "the romance with psychiatry" (5), model legislation was drafted that dispensed with criminalistic terminology, jury trials, and judicial procedures to decide the issue of commitment (6, pp. 454–475). New statutory provisions permitting commitment for varying periods of time based wholly on psychiatric certifications (rather than on judicial determinations) reflected this approach.

More recently there has been another shift, involving a "significant disenchantment . . . with both restrictive and punitive legal barriers and excessive reliance on psychiatric judgment" (5). There has been a growing attack on what is regarded as paternalism, particularly on the part of institutional administrators and clinicians. In contrast to the law of the past hundred years, which focused primarily on commitment procedures, increasing attention is now being paid to the rights, treatment, and living conditions of the mentally ill and retarded *after* they have been admitted to mental health facilities.

With the widespread growth of the open-door policy in mental health facilities and with the increase in voluntary admissions during the past two decades, we have entered an era in mental health law that might be called a "romance with the community." Increasingly, the relationship between the mental patient and the mental health facility is taking on a contractual character with options on both sides of the contract. Thus at least eight states (6, p. 19) now provide "informal" or unconditional voluntary admission in which either the patient or the facility can terminate treatment at any time. All states but one provide for conditional voluntary admission, in which the patient agrees to give notice of his intention to terminate treatment (6, p. 19). The facility may then initiate judicial proceedings to commit the patient involuntarily if the commitment standards are met. Thus the courts are being used less frequently, the dignity and autonomy of the patient are enhanced, and mental hospitalization is further decriminalized.

JUDICIAL DECISIONS

Law is interpreted, modified, changed, and expanded both through statute and through judicial decision. As a general rule, broad, prospective legal change is effected through legislation; decisional or case law is traditionally more limited and remedial, determining the rights and obligations of particular persons or parties. Only in recent years have the courts been used to any significant degree as a forum for the mentally ill and mentally retarded. While historically there have been decisions relating to wrongful detention in mental hospitals (7, 8), the status, rights, and treatment of the mentally disabled have only recently become a matter of judicial concern.

The last two decades have been characterized by the establishment and expansion of civil (9), criminal (10), and consumer (11) rights through judicial decision. This general model of heretofore powerless and neglected groups in society, utilizing the judicial system as both a forum for the expression of legitimate grievances and as an effective and responsive vehicle for social change, is now being adopted by and for the mentally disabled.

[1] The first private facilities were Friends Hospital, Philadelphia (1817); Bloomingdale Asylum, N.Y. (1817); and McLean Asylum, Mass. (1818). Among the early public institutions were the hospital at Williamsburg, Va. (1773), Eastern Kentucky State Hospital and South Carolina State Hospital (1824), and Worcester State Hospital, Mass. (1833).

Class Actions

Legal efforts on behalf of the mentally ill and retarded have been procedurally facilitated by use of the "class action" mechanism in particular. In essence, class actions are representative law suits brought by a group of individuals who stand in the shoes or represent the interests of an indeterminate number of persons sharing the same legal claim against an alleged common wrongdoer or defendant. In 1966, as part of a general revision of the Federal Rules of Civil Procedure, Rule 23 was rewritten to permit broader application of the class suit. Subsequently, 44 states patterned their state procedural rules on the federal model, creating greater uniformity in and accessibility of class actions at both the state and federal levels. (Mississippi, New Hampshire, Rhode Island, Tennessee, Vermont, and Virginia do not currently have statutory provisions governing class actions.) Generally speaking, these revisions in the procedural requirements for class actions give the courts greater discretion to permit such suits when it is in the interests of justice to do so. Recent examples of permissible classes of plaintiffs include shareholders in a company, consumer groups, and mental patients.

Class suits were originally utilized to provide legal recourse to persons who had relatively small but legitimate claims and who lacked the financial resources to pursue such an action unless they were able to amalgamate claims with similarly injured persons. However, "the modern approach to class actions is encouraging litigation where a remedy is theoretically, but not practically available—as in consumer class actions where each class member has been injured in a small way, but where the aggregate injury is great indeed" (12). The current emphasis is thus placed on the potential impact of the remedy, rather than on the financial ability to bring suit (although this continues to be of concern).

There is no uniform standard or rule of thumb for how many individuals are necessary to bring a class suit. "Of far greater importance is the adequacy of representation by those who would be representative plaintiffs" (12). This requires an "ascertainable class" or a clearly defined group of persons with common interests (13). The facts and law that would permit recovery to one member of the class bringing the suit must permit recovery to all members of the class. This is essential because of the operation of the legal principle of res judicata, which makes the court's decision binding on the entire class, whether it is favorable or not.

The type of issue involved in the case may be determinative of the appropriateness of the class action mechanism: "A civil rights case is much more likely to gather judicial support in borderline cases than is an ordinary suit for fraud" (12). Moreover, underlying the concept of the class action is a notion of equalizing the positions of the parties: "To permit the defendants to contest liability with each claimant in a single, separate suit would, in many cases, give the defendants an advantage which would be almost equivalent to closing the door of justice to all small claimants. This is what we think the class suit practice was [designed] to prevent" (14, p. 90).

In terms of recovery, the class action is more effective in obtaining injunctive relief (i.e., a court order that the defendant either cease or take particular actions) than in awarding compensation or monetary damages. This is determined in large part by the nature of the action; those persons whose interests are represented and in fact litigated in a class suit may, in reality, be unknown and therefore unable to share in their legitimate portion of a monetary award. The difficulty of determining a single sum as damages in cases where the divider is unknown is obvious. In the area of mental health and retardation the legal relief sought by mental patients has most often been injunctive in nature (e.g., that the physical facilities and treatment services of institutions be improved); therefore the class action can be a particularly appropriate and effective vehicle for such purposes.

While a comprehensive compilation of judicial decisions relating to the mentally disabled is beyond the scope of this paper, we will attempt to categorize and evaluate the impact of some of these decisions. It should be pointed out that case law is wholly binding only within the jurisdiction of the court rendering the decision; consequently, a decision of one state need not be followed in another. On the other hand, the common law is based on precedent; the influence and impact of a particular decision, especially in a substantive area where there is little case law, can be impressive.

Right-to-Treatment Decisions

Of major significance is the recent line of cases recognizing the right to treatment of institutionalized mentally ill and mentally retarded persons. Beginning with the landmark decision in *Rouse v. Cameron* (15) in 1966, the District of Columbia Circuit Court of Appeals held that mental patients committed by criminal courts had the right to adequate treatment. The mental condition of such persons had resulted in their being found not guilty by reason of insanity; in the absence of criminal responsibility, punishment and incarceration were precluded. Although criminal commitment to a high-security mental hospital for therapeutic care and treatment would be both appropriate and constitutional, such confinement *without adequate treatment* was held tantamount to incarceration, thus transforming the hospital into a penitentiary. The *Rouse* decision stated that "the purpose of involuntary hospitalization is treatment, not punishment"; adequate treatment was in effect held to be the sine qua non of such criminal commitments. Two years later, again in the context of criminal commitments to mental hospitals, Massachusetts extended the right to treatment to persons found incompetent to stand trial (16).

In 1971, in response to a class action, an Alabama Federal District Court further extended the right to adequate treatment to *all* mentally ill and mentally retarded persons who were in institutions involuntarily, whether their commitments were under civil or criminal procedures (1). Moreover, the court based its decision on a constitutional guarantee of the right to treatment: "To deprive any citi-

zen of his or her liberty upon the altruistic theory that the confinement is for humane therapeutic reasons and fail to provide adequate treatment violates the very fundamentals of due process" (1, p. 785).

Dissatisfied with the state plan for improvement of facilities required by the court in its first order (1, p. 785) and utilizing contributions and suggestions of a panel of national mental health experts, the court issued an order in April 1972 (17) that detailed the criteria for adequate treatment in three areas: 1) a humane psychological and physical environment, 2) a qualified staff with a sufficient number of members to administer adequate treatment, and 3) individualized treatment plans. However, the focus in the 1972 *Wyatt v. Stickney* order is exclusively on the allocation and expenditure of state funds for mental health institutions. Given limited resources for mental health services, the widespread application of the explicit and comprehensive *Wyatt* standards and requirements could be antithetical to the general movement toward community alternatives to institutional care. In October 1972, Judge Johnson, who wrote the *Wyatt* opinion, further applied its holding to require adequate medical treatment, including psychiatric services for prison inmates (18). In sharp contrast to these holdings a federal district court in the same Circuit (Georgia) held that determinations regarding the quality of mental health services and the adequacy of treatment rest with the "elected representatives of the people" and not with the courts (19).

These cases involved patients involuntarily committed under civil or criminal law. The increasing utilization of voluntary admissions to mental hospitals substantially mitigates the "incarceration" component of involuntary hospitalization. However, while the issue of adequacy of treatment for voluntarily admitted patients has not yet been addressed by the courts, there is no medical, legal, or ethical justification for compromising the quality of care and treatment at a mental health facility because of the legal status of the recipient. Minimum standards for adequate treatment should be no different, and certainly no lower, for voluntary patients than for involuntary patients. The constitutional guarantee of equal protection under the laws, particularly when one is dealing with state facilities, should mandate such a result.

Mental Retardation Law Suits

While *Wyatt v. Stickney* encompassed the rights of both the mentally ill and mentally retarded, there have been a number of recent cases that have specifically focused on the legal interests of the mentally retarded. Class actions on behalf of mentally retarded residents in state facilities have been brought in New York (20, 21), in Massachusetts (22), in Illinois (23, 24), and unsuccessfully (pending appeal) in Georgia (19). As in the *Wyatt* model, the plaintiffs seek the establishment and implementation of standards for adequate treatment and the improvement of the physical plant and treatment services. In the area of patient labor, class suits are under way in Tennessee (25) and in Florida (26) alleging the unconstitutional servitude of mentally retarded residents required to perform services in state facilities.

In an important decision in Pennsylvania in 1971, a federal court ordered that all mentally retarded children there be accorded access to a free public education program appropriate to their learning capacities (27). The potential impact of this decision on the custodial mental retardation facility could be enormous. In the District of Columbia plaintiffs in a class action had been suspended from school because of mental, behavioral, physical, or emotional handicaps or deficiencies. The court initially ordered the reenrollment of the named plaintiffs and the identification and readmission of other members of the class. In March 1972, judgment was made in favor of the plaintiffs, although the detailed order has not yet been handed down (28). In California a suit is currently being brought on the grounds of denial of education to a mentally retarded child in response to the state's attempt to terminate her placement in a state facility because of her "noneducability" (29). To date, the court has enjoined the state from interfering with the child's education until a final judicial determination is made.

Inaccurate and arbitrary classification and placement of mentally retarded children and the denial of their right to education is the basis for pending law suits in California (30), Louisiana (31), and New York (32). Other pending right-to-education suits are being brought in Michigan (33) and in North Carolina (34); others deal with autistic children (California) (35), special education in general (Delaware) (36), and emotionally disturbed children (Massachusetts) (37).

In addition to the broad categories of the right-to-treatment and mental retardation cases discussed here there have been several decisions delineating other rights of the mentally disabled. In *Commonwealth v. Wiseman* (38) the Massachusetts Supreme Judicial Court established the right to privacy of institutionalized mental patients and prohibited their commercial exploitation. This was particularly significant since there had been no legal recognition of the right to privacy for anyone in Massachusetts until this decision (39, 40). In New York a federal court held that an involuntarily committed mental patient whom the court had not found incompetent was constitutionally guaranteed the right to refuse certain kinds of treatment because of religious beliefs (41). Still another court held that it would not permit the sterilization of a mental retardate who had given birth to two illegitimate children because the patient was unable to give consent (42).

While there are decisions and statutes in other jurisdictions that conflict with and contradict these cases, the examples cited here do represent some of the current judicial thinking in the area of mental health and retardation. Moreover, it is suggested that these decisions will have an impact beyond their jurisdictions. While the *Rouse* decision was narrowly grounded in a statutory right to treatment, subsequent decisions have not been legislatively derived.[2] Partially in response to the right-

[2] *Wyatt v. Stickney* (1) was based on constitutional grounds.

to-treatment decisions, legislative proposals have begun to reflect this legal concept (43) [Fla Stats ss 394.459 (1), (2), (3)].

The initial *Wyatt v. Stickney* order (1) required the State of Alabama to devise and submit a plan to the court for upgrading state institutions for the mentally disabled. This mechanism of administrative response and solution under judicial supervision has been emulated elsewhere (22, 44). In New York State the public furor resulting from the Willowbrook exposé and lawsuit (20) apparently resulted in the restoration of $5 million to the state budget. While such measures cannot be exclusively attributed to recent decisions protecting the legal rights of the mentally disabled, the impact of these landmark cases has most likely been significant.

As noted before, case law is essentially a response to past injustices and wrongs; appropriate redress is traditionally made to particular persons in particular situations. Thus judicial solutions, while occasionally broadly and innovatively applicable, are ordinarily limited in scope and tied to the past.

STATUTORY CHANGE[3]

Comprehensive and prospective legal change in protecting the rights of and providing services to the mentally disabled can be found primarily in legislative measures. In the past few years a number of states have enacted new legislation or have recodified and amended their existing statutes relating to mental health and mental retardation. An examination of some of these new laws has suggested several trends, or at least common problem areas for which legislative solutions have been undertaken. There is clearly no single or uniform method of dealing with these areas; what these new statutes have in common is a comprehensive attempt to correct the deficiencies of the past. "It is one of the happy incidents of the federal system that a single . . . State may, if its citizens choose, serve as a laboratory . . ." (45, p. 311). Here we see a number of legislative "experiments" going on simultaneously, with the potential of providing us with a number of innovative ways to improve the mental health system.

While the new mental health laws discussed in this paper deal with many of the same problem areas, they vary greatly in their length and degree of detail. Massachusetts, following the suggestion that "less law rather than more law may be the answer for the future" (46), recently enacted a relatively short mental health statute. This statute, in many instances, assigns regulatory authority to administrators to establish detailed standards, criteria, and requirements. For example, the definition of mental illness for the purposes of admission and involuntary commitment to mental health facilities is left to articulation in administrative regulations [Mass Gen Laws, ch 123 s 2; Mass Dept of Mental Health Regulation 1]. After promulgation, such administrative regulations have the force of law (47, p. 309). In addition, they are a more flexible mechanism and more easily amended than statutory law.

On the other hand, states such as New York and California have relatively lengthy and specific statutes, in addition to which regulations are also promulgated. While public hearings are required for the adoption of rules and regulations, it is probably fair to assume that legislation is subject to greater accessibility and public scrutiny and to more rigorous accountability than are regulations.

No value judgment should be made regarding the length and specificity of a statute. There are advantages and disadvantages to each approach. What is of primary importance is careful drafting, consistency, and comprehensiveness.

Areas of Change

The trends and changes in the new mental health statutes are generally in response to two broad problem areas: 1) the debilitative and dysfunctional effects of long-term custodial institutionalization, and 2) the neglect and, indeed, the abrogation of the rights and personal dignity of individuals committed to hospitals for indeterminate periods of time. The thrust of new mental health legislation has thus been toward shorter hospital stays, community alternatives to institutionalization, legal protection of the patient's rights, and substantial guarantees of the quality of treatment while under the care of the facility. We shall consider these changes in greater detail later in the paper.

New Statutory Trends Related to Institutionalization

Variety of admission statuses. Less than 25 years ago "the World Health Organization reported that only 13,848 of 138,253 admissions to state mental hospitals in the United States, slightly more than 10%, were voluntary" (6, p. 17). Stated conversely, almost 90 percent of these patients had been involuntarily committed to mental institutions. In contrast to this almost monolithic system of hospitalization, more recent statutes provide a number of alternative routes to hospitalization and a variety of admission statuses. In addition to involuntary admissions there are the informal voluntary admissions based on the general hospital model [e.g., Pa Stats Title 50 s 4402; Ill Stats ch 91½ s 4-1; NY Mental Hyg Law s 31.15]. Another (and more common) voluntary admission status is a limited or conditional one in which release requires written notice and a lapse of generally three to ten days [e.g., Pa Stats Title 50 s 4403; Fla Stats s 394.465; Ga Code s 88-503; NY Mental Hyg Law s 31.13]. There are also pretreatment statuses such as emergency [e.g., Fla Stats s 394.463 (1); Ga Code s 88-504; Ill Stats ch 91½ s 7-1; Minn Stats s 253A.04], diagnostic [Pa Stats Title 50 s 4406], and evaluative [Fla Stats s 394.463 (2); Ga Code s 88-505.2; Calif Welf & Instits Code ss 5200, et seq] admissions that are usually of short duration and often precede admission for planned care and treatment.

[3] Mental health legislation in the following states was reviewed and regarded as representative for purposes of the statutory section of this paper: California, Florida, Georgia, Illinois, Massachusetts, Minnesota, Missouri, New York, and Pennsylvania.

Several legislative provisions explicitly state a presumption or a preference for voluntary admissions. "It shall be the duty of all state and local officers . . . to encourage any person suitable therefor and in need of care and treatment for mental illness to apply for admission as a voluntary or informal patient" [NY Mental Hyg Law ss 31.21(a), 31.23; see also Fla Stats s 394.465; Ga Code s 88-503]. In Massachusetts the right to conditional voluntary status and notice of that right on admission are absolute [Mass Gen Laws ch 123 s 12(c)].

The diversity in admission statuses, as well as the documented increase in the numbers of voluntary admissions to mental hospitals (6, pp. 17, 48), indicates substantial legislative effort to put an end to hospital stays of unlimited duration in which the patient could not initiate his discharge or his release. It also represents an increasing sophistication and an accommodation of the hospitalization episode to the particular needs of the particular patient. Finally, it represents enhanced emphasis on the rights of mentally disabled persons to freedom of movement and to self-determination.

Classification of mentally ill and mentally retarded persons. One of the disparate elements of the new mental health statutes is their inconsistent manner of classifying or categorizing mentally ill and mentally retarded persons. Nowhere is the terminology uniform from one state to another. This is partly the product of the differential variety of admission statuses available under the new laws. There are other distinctions as well. For example, eligibility for consenting admission to facilities often depends on age, ranging from 14 years in Georgia [Ga Code s 88-503] and Florida [Fla Stats s 394.465] to 18 years in most states [e.g., Pa Stats Title 50 s 4402, et seq; Ill Stats ch 91½ s 5-2; Minn Stats s 253A.03]. This disparity reflects the ambiguity in classifying adolescents as either children or adults.

In the past the law has generally not differentiated among disabilities; mental illness, epilepsy, mental retardation, and senility have often been jumbled together into a single statutory provision. Of special significance in recent legislative reform has been the degree of awareness and sophistication in particularizing these disabilities. For example, mental retardation has been clearly differentiated from mental illness: "A mentally retarded person may be considered mentally ill provided that no mentally retarded person shall be considered mentally ill solely by virtue of his mental retardation" [Mass Gen Law ch 123 s 1]. Moreover, the new laws specifically require the development of services that are adapted and appropriate to the needs of the mentally retarded (rather than acquiescing to watered-down mental health programs). Finally, there is awareness of variations within mental retardation: levels or degrees of retardation have now been recognized in statute and regulation [Mass Gen Laws ch 123 s 2; Mass Dept of Mental Health Regulation MR 116].

Few of the recent mental health statutes have reformed procedures relating to the category of the psychiatric offender, i.e., the mentally ill person who is within the criminal law system. Generally, provisions relating to this area will be found in the criminal statutes. With few exceptions [e.g., Pa Stats Title 50 ss 4407, et seq; Mass Gen Laws ch 123 ss 13–19] procedures governing the mentally ill criminal offender have tended to be neglected even in those states which have undergone substantial revision of their mental health statutes. There is a risk here that when civil statutes governing the mentally ill become procedurally complex or when standards for civil commitment become more restrictive, recourse to simpler criminal procedures may increase. Thus in California, with its new, restrictive civil procedures, an increase in the use of criminal procedures has been reported (49). It is a relatively simple matter to allege "disorderly conduct" or "disturbing the peace" against a mentally ill person and bring about commitment in a mental hospital based on the question of his competency to stand trial.

However, attention is being focused on this area in case law (50, 51). Indeed, a recent decision by the United States Supreme Court stated: "Considering the number of persons affected, it is perhaps remarkable that the substantive constitutional limitations on this power [to commit mentally ill persons] have not been more frequently litigated" (51, p. 737). It is likely that statutory reform will eventuate in the area of the mentally ill offender.

Limitations on involuntary commitment. Closely linked to the greater variety of admission statuses and to the increasing use of voluntary admission have been significant limitations on the wholesale use of involuntary commitment. Indeed, a primary purpose of the new California mental health law is "to end the inappropriate, indefinite and involuntary commitment of mentally disordered persons . . ." [Calif Welf & Instits Code s 5001(a)]. The statutory standard for involuntary commitment has become somewhat more stringent in a number of states, contributing to a decreasing number of involuntary commitments. In 1959, only five states restricted involuntary hospitalization to those who were "dangerous." Ten years later nine states utilized dangerousness as the sole criterion for involuntary commitment, while 18 others permitted the need for care and treatment (or the welfare or best interests of the patient or society) to serve as alternative bases to dangerousness for involuntary hospitalization (6, p. 36). In 1971, Massachusetts adopted the concept of "likelihood of serious harm" (i.e., dangerousness) as its standard for commitment [Mass Gen Laws ch 123 ss 7, 8, 12]. It should be noted that in 1971, Massachusetts specifically rejected the concept of "social harm" (other than physical harm) as a basis for commitment; prior to this time, Massachusetts had been alone in its use of this standard (6, p. 36). New York, in a statute that became effective January 1, 1973, utilizes the standard of "likelihood of serious harm" for some commitments [NY Mental Hyg Law s 31.37], while Missouri in a 1969 law introduced "dangerousness" as one of its standards for commitment [Mo Stats s 202.800].

New statutory restrictions on involuntary commitment have had an effect on the institutionalization of the mentally retarded. In Massachusetts, for example, there can be no involuntary commitment of mentally retarded per-

sons who are not also mentally ill [Mass Gen Laws ch 123 ss 1, 7(a)]. In some of the newer statutes providing for the involuntary commitment of the mentally retarded, the standard for commitment is distinct from that for commitment of the mentally ill; in New York it is limited to a person ". . . in need of inpatient care and treatment as a resident in a school, [where] such care and treatment is essential to his welfare, and [where] his judgment is so impaired that he is unable to understand the need for such care and treatment" [NY Mental Hyg Law s 33.01].

Procedurally, involuntary commitment may be accomplished through the courts or through the medical certification of mental disability by a psychiatrist. In some of the new statutes a variety of commitment mechanisms have evolved, each appropriate to the particular involuntary status involved. For example, medical certification is often utilized for brief periods of involuntary hospitalization, such as emergency care [e.g., Pa Stats Title 50 s 4405 (ten days); Mo Stats s 202.795 (five days); Minn Stats s 253.04 (three days)]. (One court has held that involuntary commitment by medical certification for an indeterminate period of time is unconstitutional [52].) Judicial commitment usually relates to longer commitments and is accompanied by the full panoply of legal protections such as notice, hearing, representation by counsel, and so forth [Mass Gen Laws ch 123 s 5; Minn Stats s 253A.07; Ill Stats ch 91½ ss 8, 9; Ga Code s 88-507, et seq; Fla Stats s 394.67]. Falling somewhere between these procedures is a quasi-judicial or administrative commitment carried out by hearing officers [Fla Stats s 394.457 (6); Ga Code s 88-506]. It should be noted that administrative commitment is subject to judicial review [Fla Stats s 394.547 (6) (e)] (6, p. 57).

These statutory measures serve to restrict the availability and unnecessary utilization of involuntary commitment for long periods of time. In so doing they force closer scrutiny of the clinical status and particular needs of the mentally disabled individual and militate against the neglect of institutionalized patients.

Orientation of facilities toward the community. A number of the new mental health laws reflect the general shift in mental hospital treatment toward "open-door" policies and the effort to abolish locked and neglected back wards. New statutory provisions set forth explicit internal procedures for patient management and for administration of the institutions. For example, some provisions were designed to result in shorter patient stays, as we discussed previously. Others mandate periodic clinical review [Ill Stats ch 91½ s 10-2; Minn Stats s 253A.17-(7); NY Mental Hyg Law s 15.03; Mass Gen Laws ch 123 s 4]. This involves a close, individualized evaluation of a patient's progress, with a view toward discharge and continued treatment in the community rather than in the institution. The Massachusetts statute specifically requires the consideration of alternatives to hospitalization in its periodic review provision [Mass Gen Laws ch 123 s 4], while the Illinois law sets forth a similar requirement in its commitment hearings [Ill Stats ch 91½ s 9-6]. It is likely that these provisions will contribute to an increasing patient turnover and a decreasing hospital census. This should make possible a reallocation of resources, perhaps directed toward community alternatives.

As a result of the impetus of the federal Community Mental Health Centers Act of 1963 (53, 54), more than 300 community mental health centers have been established throughout the country. Some recent statutes have recognized the halfway house and community residence as viable and homelike alternatives to the traditional hospital as well [Minn Stats s 245.691; Calif Welf & Instits Code ss 5115, 5705.5; NY Mental Hyg Law s 11.29; Mass Gen Laws ch 19 s 29; Mass Dept of Mental Health Regulation 5.2; Mo Stats s 202.645; Fla Stats s 393.015; Minn Stats s 252.021]. Advocates of the community residence model argue that rigorous state regulation and licensure of these programs risk their conversion into "mini-institutions." On the other hand, legislative recognition and approbation of their intermediary function further encourage a change in the role of the state hospital and state school. Rather than providing custodial care for chronic patients, the large mental institutions may well be transformed into crisis-oriented facilities for more acutely ill patients.

The orientation of mental health programs toward the community, as well as the increasing use of voluntary hospitalization, represents acceptance into and by society of its mentally ill citizens and narrows the differences in legal and social status between the mentally healthy and the mentally ill.

Trends Related to Patients' Rights

Explicit statutory recognition in recent legislation of the civil and personal rights of the mentally ill and mentally retarded not only constitutes significant and needed reform, but also indicates the kinds of discrimination and illegal restrictions that had been placed on the mentally disabled in the past. Enumerated in recent legislation are such rights as that to communicate with persons outside the facility (via correspondence, telephone, and visits) [e.g., Pa Stats Title 50 s 4423; Mo Stats s 202.847; Fla Stats s 394.459 (4); Ga Code s 88-502.5; Ill Stats ch 91½ s 12-2; Minn Stats ss 253A.05, 253A.17; Calif Welf & Instits Code s 5325; NY Mental Hyg Law 15.05; Mass Gen Laws ch 123 s 23]; to keep clothing and personal effects [e.g., Fla Stats s 394.459 (5); Ga Code s 88-502.6; Calif Welf & Instits Code s 5325; NY Mental Hyg Law s 15.07]; to religious freedom [e.g., Pa Stats Title 50 s 4423; Minn Stats s 253A.17]; to vote [Fla Stats s 394.459 (6); Mo Stats s 202.847; Ga Code s 88-502.7; Ill Stats ch 91½ s 9-11; NY Mental Hyg Law s 15.01; Mass Gen Laws ch 123 s 25]; to be employed if possible [e.g., Pa Stats Title 50 s 4423; Ga Code s 88-502.8; NY Mental Hyg Law s 15.09]; to manage or dispose of property [Mo Stats s 202.847; Ill Stats ch 91½ s 9-11; Minn Stats s 253A.18]; to execute instruments such as wills [Mo Stats s 202.847; Minn Stats s 253A.18; Mass Gen Laws ch 123 s 25]; to enter contractual relationships [Mo Stats s 202.847; Ill Stats ch 91½ s 9-11; Minn Stats s 253A.18; Mass Gen Laws ch 123 s 25]; to make pur-

chases [Mo Stats s 202.847; Minn Stats s 253A.18]; to education [Fla Stats s 394.459 (7); Ga Code s 88-502.9; NY Mental Hyg Law s 15.11]; to habeas corpus [e.g., Pa Stats Title 50 s 4426; Ill Stats ch 91½ s 10-6; Calif Welf & Instits Code s 7250]; to independent psychiatric examination [Pa Stats Title 50 s 4423; Fla Stats s 394.459 (3) (b)]; to civil service status [Ill Stats ch 91½ s 9-11; NY Mental Hyg Law s 15.01]; to retain licenses, privileges, or permits established by law such as a driver's or professional license [Minn Stats s 253A.18; Ill Stats ch 91½ s 9-11; NY Mental Hyg Law s 15.01]; to sue and be sued [Minn Stats s 253A.18]; to marry [Minn Op AG 1008 Sept 22, 1968; Mass Dept of Mental Health Regulation MH 16]; and not to be subject to unnecessary mechanical restraints [Mo Stats s 202.843; Ga Code s 88-502.4; Minn Stats s 253.17].

Mental illness does not necessarily impute incompetency in exercising one or more of these rights, and incompetency requires specific judicial determination. A number of statutes clearly differentiate between mental illness and mental incompetency [e.g., Mo Stats s 202.847; Mass Gen Laws ch 123 s 25; Fla Stats s 394.459 (1)] and make reference to this distinction in their catalog of patients' rights [e.g., Ill Stats ch 91½ s 9-11; NY Mental Hyg Law s 29.03].

The right to legal representation. The constitutional guarantee of the right to counsel or legal representation, which originated in the area of criminal law (55), has been incorporated into a number of new mental health statutes to protect the rights of patients in commitment hearings, including the appointment of counsel for indigent persons [e.g., Fla Stats ss 394.467 (2) (d), 394.467 (3), 394.473; Ga Stats ss 88-502.12, 88.503.3, 88.506.6; Ill Stats ch 91½ s 9-4]. The participation of an attorney representing the interests of the patient precludes the reality or the appearance of railroading commitment and establishes a true "adversary" setting, ensuring close adherence to statutory commitment standards.

Mechanisms for review, apprisal, and explanation of patients' rights are being introduced in several states. New York, for example, has established the Mental Health Information System, a court-affiliated service to review the admission and retention of all patients and to inform and advise patients of their rights [NY Mental Hyg Law s 29.09]. A California court has instituted the use of a nonprofit legal services group to apprise involuntarily certified patients of their legal rights (56). In Minnesota, review boards examine the admission and detention of patients [Minn Stats s 253A.16], while Massachusetts requires the designation of a "civil rights officer" in each mental health facility to assist the patient in exercising his rights [Mass Dept of Mental Health Regulation MH 16]. In addition, apart from traditional guardianship and conservatorship provisions, new and more flexible forms of patient representation or patient advocacy have been statutorily established [Calif Welf & Instits Code s 5350; Fla Stats s 394.459; Ga Code s 88-502.19; Ill Stats ch 91½ ss 9-6, 9-7].

Legal representation of patients' rights and interests indicates a fundamental change in attitudes toward the mentally disabled: no longer is the mental patient passively subject to the legal, economic, and personal consequences of his illness, but may, with legal assistance if necessary, affirmatively and actively continue to control his own life.

Privacy and confidentiality. Protecting the privacy of mental patients, as well as the confidentiality of their communications and medical records, has become a significant legal concern. The "right of privacy" implies the right of the individual to keep some information about himself or access to his personality (as by a photograph or personality test) completely secret from others. "Confidentiality," on the other hand, presupposes disclosure of certain information to another person; however, the communication of such information is limited to specifically authorized parties. "Privileged testimonial communication" is an evidentiary concept, permitting the patient or client to prevent his physician, psychologist, etc., from disclosing confidential communications in court or in other legal proceedings.

All but three states (Rhode Island, Texas, and Wisconsin) recognize the right of privacy in some form (57, footnote 3), while approximately two-thirds of the states have enacted physician-patient testimonial privilege statutes (58). Interestingly enough, physician-patient testimonial privilege statutes in Connecticut [Gen Stats of Conn Title 52-146 (d), (e), (f)] (59, footnote 8) and in Massachusetts [Mass Gen Laws ch 322 s 203] protect only communications between psychotherapists and patients—one of the few areas where the legal interests of the mentally disabled have been given priority. In addition, most of the new mental health statutes specifically protect the confidentiality of patient records [Pa Stats Title 50 s 4602; Fla Stats s 394.459 (8); Ga Code s 88-502.10; Ill Stats ch 91½ s 12-3; Minn Stats s 246.13; Mass Gen Laws ch 123 s 36; Calif Welf & Instits Code s 5328 (cf. s 5328.2); NY Mental Hyg Law s 15.13]. The Massachusetts statute goes on to protect patients "from commercial exploitation of any kind. No patient shall be photographed, interviewed or exposed to public view without either his express written consent or that of his legal guardian" [Mass Gen Laws ch 19 s 29(f)].

Informed consent. Another issue relating to patient rights is the ability or capacity of the mentally disabled individual to give informed consent to his "voluntary" admission, to particular kinds of treatment or therapy, to surgical procedures, or to scientific research (including interviews, behavioral observation and testing, administration of drugs, and so forth). The case law regarding a mental patient's capacity to consent is ambiguous, and decisions support almost any position.[4] There are a few statutory provisions requiring patient consent to surgery and to specific modalities of treatment such as electroconvulsive therapy [Minn Stats s 253A.17; Calif Welf & Instits Code ss 5325, 5325.5; NY Mental Hyg Law s 15.03; Mass Gen Laws ch 123 s 23].

With regard to capacity to give informed consent to

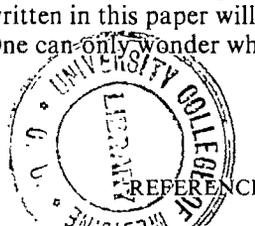
[4] Compare *Wilson v. Lehman* (60) and *Lester v. Aetna Casualty & Surety Co.* (61).

voluntary admission, some states have avoided the issue and created admission statuses such as "nonobjecting" [Ga Code s 88-506; NY Mental Hyg Law s 33.25] or "voluntary commitment" [Pa Stats Title 50 s 4403]. Finally, there is almost no statutory or case law relating to consent to scientific research (62). Federal (63) and state (64) guidelines requiring patient consent to participation in research are essentially hortatory but may indicate the direction of future statutory or regulatory amendment.

Statutory right to treatment. Corresponding to the growing body of case law relating to the right to treatment, recent legislation has begun to articulate substantive guarantees of adequate and humane treatment:

> Each patient in a facility shall receive treatment suited to his needs which shall be administered skillfully, safely, and humanely with full respect for his dignity and personal integrity. Each patient shall receive such medical, vocational, social, educational, and rehabilitative services as his condition requires to bring about an early return to his community [Fla Stats s 394.459 (3); also see Mo Stats s 202.840; Ga Code ss 88-502.2, 88-502.3; Ill Stats ch 91½ s 12-1; NY Mental Hyg Law s 15.03].

Such guarantees would appear to be enforceable in court, if necessary. However, criteria for judicial assessment of the adequacy of treatment received remains a problematic area (65).



CONCLUSIONS

In one sense we have now come full circle in mental health law since the days of the "moral treatment" of the mentally ill. In those days admission to mental hospitals was selective and the unresponsive patient was turned away. Treatment was adequate, but only for the few. Now we are required to provide adequate treatment, but for the many. Fortunately, with the significant advances in the treatment of the mentally ill in the past 20 years, we should be able to make accelerated progress toward such a desideratum. This will require increased allotment of public resources for the mentally ill and the mentally retarded. However, much can be accomplished by the reallocation and more productive utilization of the resources we now have.

The role of the law that has emerged in recent years may be regarded as catalytic toward improving care and treatment for the mentally disabled. If some of the new statutes and case law appear to be excessively rigid or burdensome in their implementation, or if these reforms appear at times to be advanced by overly aggressive and overzealous lawyers, it is well to remember that there is no conflict regarding the ultimate ends to which all this energy is directed. Change is painful, but we know that it is both necessary and inevitable if we are to have progress.

It matters greatly, however, what the impact of change really is. It is of fundamental importance that the effects of these changes on the quality of people's lives and health be monitored carefully. Empirical follow-up of changes in mental health law is badly needed, and little has appeared in either the psychiatric or the legal literature. It is of great significance that the United States Supreme Court itself, beginning with the landmark school desegregation decision of 1954 (9) and most recently in *Jackson v. Indiana* (51) found such empirical studies to be persuasive in its decision making.

In closing we again underscore the dynamic, evolving nature of mental health law and the complex series of "experiments" that are now going on in this area. What we have written in this paper will therefore become dated rapidly. One can only wonder what new legal "romance" awaits us.

A Hospital Riot: Its Determinants and Implications for Treatment

BY RICHARD C. MAROHN, M.D., DIANE DALLE-MOLLE, R.N., M.S., DANIEL OFFER, M.D., AND ERIC OSTROV

Several factors were responsible for a riot on an inpatient treatment unit for delinquent adolescents: individual dynamics of patients and staff, group problems of patients and staff, and issues involving the entire patient-staff group. The unit is viewed as an open system comprising the individual dynamics of staff and patients as well as their interrelationships. Achieving and maintaining internal homeostasis are essential to that organism. The authors discuss the implications of their findings for hospital treatment.

WHEN HALF OF THE PATIENTS on an inpatient treatment unit for delinquent adolescents rioted, we took the opportunity to study the determinants of this collective disturbance. This paper describes the pertinent literature, the population of the unit, the riot and events leading up to it, interviews with patients and staff, a discussion of the riot as the interaction of an open system, and the implications for hospital treatment.

In the literature, treatment innovation, staff disorganization, and staff-patient boundary breakdown are described as setting the stage for rioting.

An innovative, more humanitarian approach may create destructive anxiety in both patients and staff if it is not worked through. An early description of this phenomenon appears in the book *Branch Street* (1). It relates that following the liberalization of policies by the leader of a London settlement house without concurrence of the staff, the deprived and delinquent children rioted, vandalized the house, and forced its closing. Previous work by one of us (R.C.M.) in a prison setting (2) led him to believe that riots may occur when institutional change happens without being fully accepted by either the staff or inmates. In a larger sense most social riots in the United States have been the result of the "reconstructivists" trying to effect change and the "nativists" trying to maintain the status quo, with no opportunities to work the issues out constructively (3).

In a treatment setting for delinquent girls Ruth Eissler (4) found that although individual delinquency seemed to be related to personal inner turmoil, mass delinquency was due to "dissension or tension among the supervising staff." The collective disturbances studied by Stanton and Schwartz (5) and by Offer and Barglow (6) all resulted in part from staff disorganization. The necessity of distance and the inadvisability of too much familiarity between staff and patients have been amply documented (7). If the gap narrows, adolescents will reestablish it themselves (8), often by provoking a limit-setting response. When patients test the limits of their omnipotence and the staff fails to respond realistically, riots result (9). Blurring of staff-patient boundaries may stimulate patient fantasies for intense parental care and closeness and may lead to panic (10) or some kind of assaultive behavior (4).

SETTING

The Illinois State Psychiatric Institute is a 150-bed state hospital devoted to training, research, and service. The Delinquent Adolescent Program (Michael Reese Unit) is a closed ten-bed research and treatment ward providing psychiatric, psychological, medical, nursing, and social services; activity therapy; school; and vocational counseling to hospitalized delinquents. The unit serves not only as the site of a research project (11–13), but also as a model for treatment innovation. It accepts male and female patients 13 to 17 years of age who are not psychotic, mentally retarded, or brain damaged. Delinquency is defined as overt or covert violation of the law and includes such offenses as theft, assault, vandalism, sexual promiscuity, running away, truancy, and drug abuse.

Most of the patients have had contact with the police, and many have already been held at detention centers or are on probation. Their behavior must be severe enough to necessitate hospitalization or institutionalization. The average length of stay is six months, and each patient is involved in individual psychotherapy, as well as group and family psychotherapy when indicated. The milieu program is structured around school, activities, commu-

Revised version of a paper presented at the 125th annual meeting of the American Psychiatric Association, Dallas, Tex., May 1–5, 1972.

Dr. Marohn, Ms. Dalle-Molle, and Mr. Ostrov are with the Illinois State Psychiatric Institute, 1601 West Taylor St., Chicago, Ill. 60612, where Dr. Marohn is Director and Mr. Ostrov is Research Associate, Adolescent Program, and Ms. Dalle-Molle is Milieu Staff Supervisor, Delinquent Adolescent Program. Drs. Marohn and Offer and Mr. Ostrov are also with the Psychosomatic and Psychiatric Institute, Michael Reese Hospital, Chicago, Ill., where Dr. Marohn is Associate Attending Psychiatrist, Dr. Offer is Associate Director, and Mr. Ostrov is Research Associate.

This work was supported by Illinois Law Enforcement grant A70-15.

The authors wish to acknowledge the assistance of Mr. Thomas Rosenwein, Research Assistant, Delinquent Adolescent Program, Illinois State Psychiatric Institute.

TABLE 1
The Delinquent Population

Patient	Age at Time of Admission	Socioeconomic Status (14)	Referral Source	Reasons for Referral
Rioters				
Donna A.	17	3	Mother	Dropout, disobedience to parents, sexual promiscuity, car theft, petty theft, drug abuse, runaway
Sam G.	16	4	Probation officer	Disobedience to parents, vandalism, breaking and entering
Mary V.	17	2	Mother and probation officer	Truancy, runaway, dropout, disobedience to parents, sexual promiscuity, prostitution
Edward Q.	14	6	Probation officer	Runaway, school adjustment problems, assaultive behavior
Stan I.	16	1	Social worker and family service agency	Runaway, car theft, homicidal threats, vandalism
Nonrioters				
Nick Q.	14	3	Private psychiatrist	Hyperactivity behavior problem in school, runaway, vandalism, breaking and entering, voyeurism
Selma E.	15	7	Probation officer	Truancy, runaway, sexual promiscuity, prostitution
Carl V.	16	5	Probation officer	Repeated car theft
Elizabeth Z.	16	2	Probation officer	Runaway, assaultive behavior, homicidal threats, sexual promiscuity
Olga O.	15	4	Probation officer	Runaway, defiance of parents

nity meetings, and limit setting. A ward staff consisting of two psychiatric nurses, seven mental health specialists (six men and one woman), and five mental health technicians (two men and three women) maintain the milieu structure. The patients living on the unit at the time of the riot are described in table 1.

THE RIOT[1]

About 7:15 one evening in the summer of 1971, after the evening community meal and the weekly group therapy session, the male specialist in charge took five patients (Nick, Selma, Carl, Elizabeth, and Olga) off the unit for activities on the first floor of the hospital. Two technicians, one male and one female, remained on the unit with Donna, Mary, Sam, Stan, and Edward, all of whom were restricted from leaving the unit for one reason or another. Sam had been sleeping through all the activities after supper. While the male technician was out on the unit, the female technician remained in the nursing station but ignored Donna and Mary, who began demanding her attention by knocking on the window. Eventually, Donna went into the music room and began breaking records. Mary soon joined in.

The female staff member, who described herself as "frightened and shaking all over," admonished them to stop, which they did temporarily. But later they resumed, and Edward, who now found himself "really getting along with the other kids," joined in. Sam, awakened by the noise, joined Stan in watching television in the dayroom adjacent to the music room. When Edward threatened to throw a record at the male staff member he was taken to his room, where he began shoving his furniture about. Eventually he calmed down and returned to the dayroom. The music room was then locked. Donna and Mary began climbing on chairs and tables, saying that they were "hyper." Mary began teasing Sam by tickling him and taunting him with sexual overtures. Donna and Mary mimicked both Sam and Stan, who eventually became hyper and began jumping around on furniture and yelling loudly. "All of a sudden it happened and everyone else was into it," Mary said. Several times the female staff member cautioned the patients to stop. "This is a warning period, or you will be put into restraints." Mary felt that this "just got us madder."

When Edward told the staff member to shut up, she decided that things were out of control and returned to the nursing station to call for the specialist in charge. While she was on the phone, he and the other patients coincidentally returned to the unit at about 8:15 p.m. and found the unit "in a shambles." He then summoned other staff and security police to the unit to place the patients in restraints. The five restricted patients secured chairs, bottles, and ashtrays and barricaded themselves at the end of the corridor in an attempt to resist the staff. When the other patients had returned to the unit, the rioters became even more agitated and tried to get them to join in, but they declined. The five nonrioters, the "good kids," attempted to dissuade the rioters, but failed. Edward pulled down a towel bar from the men's shower room, which Stan took away from him to use as a weapon himself. The staff advanced with mattresses to shield themselves from the flying bottles and broken glass. Sam and Stan removed themselves from the group and surrendered to the staff. Mary and Edward fought the staff fiercely, with Mary striking and biting several staff mem-

[1] This description is based on taped interviews that two of us (R.C.M. and D.D-M.) conducted with the involved patients and staff.

bers and Edward hitting and spitting. Donna sequestered herself in the girls' toilet and when confronted, struck and bit a staff member, who responded by calling her a "bitch." All the rioting patients were placed in restraints.

That night one of us (R.C.M.) interviewed the group cotherapists before advising them of the riot. As customary, the three staff members summarized and reported the evening activities; the next morning we interviewed the five riot participants; and again the next evening, the three staff members contemplated the events of the day before. These discussions were tape-recorded and evaluated.

On reflection, it was clear that the riot had been foreshadowed by a number of serious disruptions. The female staff member observed that "this has been building up for some time" and that another staff member on the weekend had prophesied that there would be trouble. The female staff member said, however, "I did not expect it from the girls." But all three agreed that Donna and Mary were definitely "behind the whole thing" and that Edward, Sam, and Stan had been involved by contagion.

Two weeks earlier nine patients had participated in a four-day camping trip with an equal number of staff members. Donna was not included because she had obtained employment in preparation for her discharge about five months hence. While camping, staff members disagreed about how to handle certain kinds of destructive behavior, as for example, what to do when Sam began to play with and eventually mutilate a frog he had found near the encampment. The camping leader saw this as horseplay, while other staff members saw it as emerging destructive behavior and loss of control. Some staff members wanted to deal with the patients' agitation by having a group meeting, while the camping leader preferred to set up a baseball game. Both were done; but staff differences persisted.

On the second night Mary burned a hole in her tent and attempted to run away, but was thwarted. Again, the camping leader and the staff members disagreed about meeting with the patients to discuss the issues. On the last day, one-to-one supervision of a group sight-seeing trip began to break down, while some staff members wondered whether they were there to enjoy the excursion themselves or whether their role was to facilitate the patients' enjoyment. In general, many staff members felt that there were no opportunities to share problems with each other or to influence the camping leader. On their return to the hospital some patients continued to test out the limits and boundaries of the staff; for example, on the day before the riot Sam punched a male staff member several times, and this had not been dealt with.

On the day of the riot one of the nine campers was discharged as planned, and she was replaced by a new patient, Olga. That evening, as usual, staff and patients ate supper together in the dayroom prior to the 5:30 to 7 p.m. weekly group therapy session. However, during the meal an occupational therapy (OT) student advised the staff member in charge that a knife was missing from the OT shop. This was discussed at supper, and it was decided that the unit would be placed on restriction until the whereabouts of the knife could be determined. That night several patients seemed eager to start the group meeting and banged on the door while staff members unlocked it. As they entered someone turned off the lights as a prank. Both cotherapists remarked later that they were uneasy about the meeting and found it very difficult to summarize the patients' interactions. The group talked about Edward and Nick's competition for Olga's attention. Carl explained periods of silence with "They are not responding because they are depressed." When Nick was asked by the female cotherapist what he wanted from the group, he replied, "sex," described later as, "maybe another underlying issue that they didn't talk about." Selma and Carl left the meeting about two-thirds of the way through and returned to the unit. The therapists generally felt helpless about what was going on.

Toward the end of the meeting there was some discussion about Debbie, an ex-patient who would be returning to the unit at 7 p.m. for her personal belongings. About one month before, Debbie had run away and was eventually discharged after failing to return. She and Donna had been close friends, much to the envy of Mary, who felt that the rivalry was "never solved." Debbie, Donna, and Mary had all demonstrated tenuous object relations and had difficulty making a commitment to treatment. Donna had turned 18 only one month before, had signed her own voluntary admission papers, and was no longer staying in the hospital by order of her parents, a situation that caused her much anxiety. She thought that Debbie was probably homesick for the hospital, but "I just hope she is happy." Mary had become quite angry when a staff member told her, "We don't even have a treatment plan for you here." She said that her treatment program was "fucked up," cried, and said, "I'm not sure if I want to get better, or can." The expected return of Debbie to the unit at 7 p.m. made several patients anxious.

After the group meeting a brief community meeting was held with the evening staff, and the staff member in charge decided to take the patients into the OT shop to look for the knife, since all insisted that no knife was really missing. In the course of the search the patients seemed to get louder, and Nick remarked that the OT student was mistaken and that the knife in question had really been kept in the nursing station. Although a similar knife was indeed found in the nursing station, there still remained some staff confusion. The OT student was unable to contact her supervisor, who had been away for several days because of a death in her family. The missing knife "scared" Stan because someone might cut himself or someone else. The staff member in charge changed his mind and decided not to keep the unit on restriction, but instead to refer the matter to the day staff the next day. He then took the five patients off the unit, leaving the other two staff members in charge.

DISCUSSION

The therapeutic milieu is an open system of component

parts interacting dynamically with each other and with the environment (15). In an attempt to achieve and maintain internal homeostasis, the milieu develops a culture and organization. The riot represents a disruption of that organizing ability in the homeostasis of the system. Individual patient dynamics, patient group problems, individual staff dynamics, staff group problems, and factors involving the entire patient-staff group all contributed to the homeostatic breakdown.

The culture of this program more closely approximates a hospital treatment unit rather than a prison or custodial institution despite the fact that when they were anxious, patients would attempt to provoke punitive staff responses and convert the staff into jailers or policemen. By and large, staff members had resisted these efforts, and the unit is seen by the staff as an active and exciting treatment facility, occupying a high status in the hospital hierarchy. Staff turnover is low, and vacant positions are quickly filled.

The closeness of a camping trip is often too stimulating for many patients, and after such an experience they need to test out whether limits and boundaries between staff and patients still exist.[2] If lacking, patients will provoke them or panic. Staff members may also find the camping experience too stimulating. Our staff members surrendered their treatment roles and became fellow campers, as evidenced by the breakdown of one-to-one supervision and by the confusion over how to transpose treatment principles from the unit to the campsite. Patients needed to test this out on their return to the unit. When a staff member was assaulted the night before and little was done, and when the staff was confused over the missing knife and the decision to restrict the unit, the patients' anxiety level rose to one of panic because they had lost the safety and reassurance of the fantasied omnipotence of the staff. Patients' acting out forced staff members to reexamine their roles and to function again as limit setters and structure providers, organizing factors in the environment.

When the staff views deviant behavior by patients as personal affronts by heretofore loving children, it is clear that roles have become blurred. Such closeness and confusion stimulate rage in object-hungry patients. Their fantasies of once again recapturing the good mother are stimulated excessively, and they become frustrated and disappointed because staff members cannot respond to their every need, even though they have seemingly promised to do so. Vandalism and assaults on the staff express such frustration and also serve to force the staff to reestablish a therapeutic distance and structure.

Patients who were taken off the unit had the opportunity to distance themselves from such closeness and dilute the intensity of the transference. But patients restricted to the unit were trapped and left with few avenues of discharge, and these very patients had already shown a lesser capacity to control and modulate their impulses. They were restricted to the unit because they had missed school or were unable to go to bed on time; they needed the structure of the unit, but this evening the unit failed them.

In the month before the riot the unit chief had been absent from the unit a good deal and had appointed an acting chief in his absence. He had not gone on the camping trip, but had appointed a second staff member as camping leader. The activities therapist, who was important to both the camp-out and the ongoing milieu structure, was now absent because of a personal loss. Both absences were felt by the staff, and they may have paralyzed the staff the night of the riot. The staff member in charge was confused about how to handle the missing knife incident. The group leaders were confused about the group interactions. The two staff members who stayed on the unit were confused about making decisions without the person in charge or even about calling him back to the unit.

The female staff member made several ambivalent attempts to intervene by warning the patients to stop and threatening them with restraints. Presenting such an alternative is ineffective in limit setting because the patients are thus invited to test the limits. This staff member was disappointed in the behavior of her favorite girls, who she believed could not possibly be doing the things she observed before her very eyes. When Edward told her to shut up, she realized that she was no longer a personal friend to the patients, but the object of intense transference. Only then did she call the person in charge back to the unit, but she did not believe that she had the authority to call for other help on her own.

The riot provoked a strong leadership response from the chief, forced the staff to reassert staff-patient boundaries, and reestablished in the milieu system a homeostatic organization in which the staff felt important enough to work productively and patients felt safe enough to grow.

Both rioters and nonrioters had alliances with their psychotherapists that ranged from poor to excellent, but the rioters had shown more breakdown of impulse control, as evidenced by their having been placed on unit restriction. In fact, during the eight days prior to the riot the rioters as a group showed considerably more delinquent behavior on the unit than the nonrioters, largely because of the activities of Edward, Sam, and Stan. Interestingly, they had been involved in the riot primarily because of hyperstimulation and contagion. Of all the ten patients the two instigators of the riot, Donna and Mary, were most liked by the staff and were not dealt with firmly when they began to act up. An earlier study of a riot (19) showed the rioters to be younger than the nonrioters, to be involved in more frequent and more serious delinquency at an earlier age, and to have presented more behavioral problems for the staff. In this study, when rioters and nonrioters are compared on the basis of socioeconomic status, age at the time of their first court hearing, number of prior arrests, number of incarcerations, and impulsivity, no differences are noted.[3]

[2] This view contrasts with the advocacy of such closeness on camping trips as therapeutic (16, 17) and the attribution of postcamping problems to depression over the loss of closeness (18).

[3] These data are available from the authors on request.

Donna, like Debbie before her, had considerable difficulty in making a commitment to treatment. Her longing for mothering from the female staff member with whom she wanted a special relationship was particularly stimulated that evening because of the anticipated return of Debbie, with whom she had been involved in a covert homosexual relationship, which was abruptly terminated when Debbie ran away from the hospital. Debbie's return stimulated in Donna confusion about her own capacity to make a commitment, anxiety about an intense relationship with a mothering figure, and once again the triangular competition between Debbie, Donna, and Mary. Donna had preferred to leave the hospital as she had often run away from her own home—in a state of disorder, anger, and disruption—rather than to deal with a gradual process of termination over the next several months. Mary was quite confused about her prognosis, and the staff was confused about her treatment plan. Debbie's return to the unit stimulated again her own confusion about whether or not she could be helped, as well as reawakening rivalrous feelings toward Debbie for Donna's favor. Both girls resolved their competition with each other by joining together in defying the female staff member and by provoking the three boys. At the same time they expressed their intense wishes for maternal control as well as their frustrations over their inability to be gratified, their treatment, and their prognosis.

The three boys, Edward, Sam, and Stan, had become involved by contagion. All had shown fragile controls of their impulses. Edward had demonstrated markedly psychotic thinking and behavior, although it had not been anticipated at admission. He had been unable to become a member of the peer group but now readily joined this new subgroup. Sam had struggled throughout his hospitalization with his own hostile and aggressive impulses and was prohibited from horseplaying on the unit. The fact that the night before the riot he had struck a staff member and this had gone without staff response must have only challenged his already tenuous impulse controls. Nonetheless, he attempted to remain aloof from the two instigating girls until their sexual provocativeness caused him to become agitated. Even then, with the show of force, he removed himself from the riotous situation. Stan has little identity of his own and little capacity for self-observation. He was frequently involved in whatever Sam did and became enmeshed in a contagious phenomenon.

IMPLICATIONS FOR HOSPITAL TREATMENT

It is necessary to maintain clear-cut staff boundaries in all phases of the inpatient treatment relationship with adolescents. Even "fun times" like camping are "work times" for staff, and they should include regular, at least daily staff meetings to discuss patient behavior and keep staff communication open. It is confusing to the adolescent when the staff befriends him in order to manipulate his behavior. It is important to maintain staff identity in the face of adolescents' demands. Therefore, staff members need time to meet with each other, to communicate feelings and thoughts openly, and to receive consistent support from each other and from the leader. A staff member must develop a strong identity as "staff" so that in his work he feels constant support and does not need to charm, seduce, bribe, or intimidate patients in order to survive in the system. The leader should communicate a definite philosophy of treatment with which the staff can work. Distinct authority lines enable staff members to test out their own limits with their supervisors and in turn enable patients to test their limits with staff.

Destructive aggression by patients, even if minor (such as flicking ashes on the floor), reflects an incipient loss of control and/or boundaries and must be taken seriously. If it is not stopped firmly, such behavior will lead to greater confusion, disruption, and contagion. It is interesting to speculate what would have been accomplished by taking Donna and Mary to their rooms as soon as they began breaking records.

Changes in policy or leadership must be discussed, worked on, and accepted by the entire working group, especially line staff. Otherwise, the ensuing confusion can easily lead to role diffusion, breakdown of communication, loss of control, contagion, and riot.

In some situations, open communication will lessen polarization and increase the likelihood of conflict resolution (20). But on the night of the riot, opportunities for communication could not be used. Daily ward meetings, regular group therapy sessions, and informal conversations on the unit or during meals are important, but they are not enough. The staff must respond behaviorally when patient behavior becomes disruptive. A homeostatic breakdown in one segment of the milieu organism must be countered with an organizing response from another segment.

Questions of the Month

The group of questions below consists of five lettered headings followed by a list of numbered statements. For *each* numbered statement, select the *one* heading that is most closely associated with it. Each lettered heading may be selected once, more than once, or not at all.

Questions 1–4

(A) Mental Health Study Act
(B) Mental Retardation Facilities and Community Mental Health Centers Act
(C) National Mental Health Act
(D) Comprehensive Health Planning Act
(E) None of the above

1. Established the Joint Commission on Mental Illness and Health
2. Passed by Congress in 1963
3. Authorized the appropriation of more than $100,000,000 for research and treatment facilities for the mentally retarded
4. Authorized the appropriation of funds to finance the total construction cost of community mental health centers

(The Questions of the Month are from the Self-Assessment Program of the APA. The answers are supplied on page 652 of this issue.)

Psychiatry and Group Medical Practice: The Diagnostic Process, Referral Patterns, and Utilization of Services

BY JAMES W. CRAWFORD, M.D., PH.D., AND SUSAN CRAWFORD, PH.D.

Group practice has emerged during the past decade as a major organizational form for the delivery of health care. Psychiatry, however, has been found to be the least inclined of the larger medical specialties toward participation in such groups. The authors compare data on diagnosis and referral patterns from several groups. They found that short-term psychiatric care is consistently associated with a decrease in the utilization of ancillary and medical services within the group practice setting.

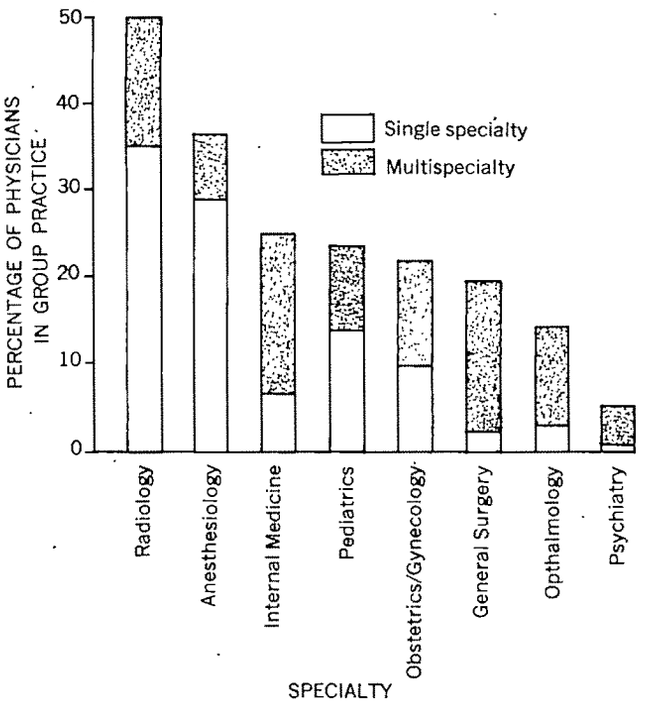
IN MORE THAN A DECADE of psychiatric practice within a medical group situation, one of us (J.W.C.) has observed that the rate of referrals to staff psychiatrists and psychologists by other members of the clinic seemed remarkably low. In addition, the number of psychiatrist colleagues who were members of other medical groups was noted to be small. An early study by Jackson supports these observations (1), as do other experiences with group clinic staff members. In view of the rapid growth of group practice during recent years, as well as experiments in the organization of manpower for the delivery of health care, it was decided to survey the experiences of other group practice clinics and to conduct a small-sample study on the practice of psychiatry within a group practice setting.

GROUP PRACTICE AND SPECIALIZATION

The group practice of medicine is an organizational form for the delivery of health care that is in large part a response to specialization and the fragmentation of services. Group medical practice is defined by the American Medical Association (AMA) as "the application of medical services by three or more physicians formally organized to provide medical care, consultation, diagnosis, and/or treatment through the joint use of equipment and personnel, and with the income from medical practice distributed in accordance with methods previously determined by members of the group" (2). During the past decade, the number of medical groups in the United States has increased by more than a factor of four (3). In 1959, AMA identified a total of 1,549 medical groups and by 1969, a total of 6,371 groups that satisfied their definition. The groups range in size from three physicians to more than 850, with an average of 6.3 physicians. The majority of the groups are small; 4,454 (85.6 percent) have fewer than seven members, while 303 (4.7 percent) have more than 16 members.

In 1969, a total of 40,093 nonfederal physicians, excluding inactive physicians, interns, and residents, were in group medical practice on a full or part-time basis. This represents 17.6 percent of the total physician population. Figure 1 indicates the percentage of physicians who are in group practice within each of the larger specialties (those with more than 9,000 physicians).

The data clearly indicate great differences among the specialties in their inclination toward group practice. Radiology and anesthesiology have the largest proportion of members in group practice—48 percent and 35 percent, respectively. Among the larger specialty groups, psychiatrists are the least inclined toward group practice, with only 955 practicing psychiatrists (6.3 percent) affiliated with a group. Among the 6,371 medical groups in the United States, only 275 (4.3 percent) have one or more psychiatrists.



PSYCHIATRY IN SINGLE-SPECIALTY AND MULTISPECIALTY GROUPS

Of the 275 specialty medical groups with one or more psychiatrists, 65 (24 percent) are single-specialty groups, i.e., groups in which all members are psychiatrists. A total of 319 psychiatrists practice in such groups. As indicated in table 1, these single psychiatric specialty groups tend to be small, ranging from three psychiatrists to 15. More than 59 percent belong to groups with three to five members, and 41 percent belong to groups with six to 15 members. In the 1969 data, which are the latest available on a nationwide basis, there were no specialty groups in psychiatry with more than 15 members. There are, however, indications of a tendency toward larger single-specialty groups; one psychiatric group in Washington, D.C., has recently been reported to have 23 members. A second survey of this universe, to be conducted by AMA in 1973, will provide longitudinal data on this aspect of organization in psychiatry.

There are a total of 2,418 multispecialty groups, i.e.,

Dr. James Crawford is Clinical Associate Professor, Department of Psychiatry, Abraham Lincoln School of Medicine, University of Illinois, Chicago, Ill. His address is 2418 Lincoln St., Evanston, Ill. 60201. Dr. Susan Crawford is Associate Professor, School of Library Service, Columbia University, New York, N.Y.

FIGURE 1
*Percentage of Physicians in Group Practice by Specialty**

*The data were obtained from Todd and McNamara (3).

groups that provide services in at least two major specialties or fields of practice. Of these, 210 (about ten percent) have one or more psychiatrists. A total of 636 psychiatrists practice in multispecialty groups. As indicated in table 1, there is a positive relationship between the size of the group and the probability of having staff psychiatrists: 23 percent are in groups with 15 or fewer members, while 77 percent are in groups with 16 or more members.

Longitudinal data on psychiatry in group practice present problems in comparison. Compilations by the American Association of Medical Clinics (AAMC) (4), U.S. Public Health Service (5), and AMA are based upon varying definitions of "group" and differing survey universes. In 1956, a review of multispecialty clinics that were members of AAMC identified a total of 37 clinics with staff psychiatrists (1).

In summary, of the major specialties, psychiatry has the smallest proportion of members in group practice, both single specialty and multispecialty. Psychiatrists tend toward solo practice. Only 6.3 percent of all practicing psychiatrists are affiliated with a group, and 4.3 percent of all of the medical groups in the United States have one or more psychiatrists. Among the 2,418 multispecialty groups, only about ten percent have psychiatric staff members.

DIAGNOSIS OF PSYCHIATRIC OR EMOTIONAL PROBLEMS IN MULTISPECIALTY GROUP PRACTICE

Three studies have yielded quantitative data on the percentage of patients diagnosed as having psychiatric problems by nonpsychiatrist physicians in group practice. These investigations, which are listed in table 2, are only generally comparable since there is variation in socioeconomic class, prepaid plan benefits, definition of psychiatric or emotional problems, criteria for selection, and the size of the population.

Goldberg, Locke, and associates (6, 8) conducted a three-and-a-half-month study to determine the extent to which physicians in departments of internal medicine, pediatrics, allergy, and dermatology of the Group Health Association (GHA) in Washington, D.C., diagnosed their patients as having psychiatric problems. Of 6,104 patients 15 years old or older, 889 (14.6 percent) were diagnosed as having "mental" or "emotional" conditions. The authors found "substantial" differences in rates of psychiatric illness reported by participating physicians that they believed reflected patient preference, physician attitudes, diagnostic skill, and the time of year the survey was done. They also found a positive correlation between the number of visits a patient made during the previous 12 months and the probability of his having a psychiatric problem. They further observed a positive relationship between rates of psychiatric problems and the length of time the physician and patient had known each other.

Fink and associates (9) studied changes in psychiatric

TABLE 1
*Psychiatrists in Group Practice by Type and Size of Group**

	Single-Specialty Group (N = 65)		Multispecialty Group (N = 219)		Total Number
Group Size	Number	Percent	Number	Percent	of Psychiatrists
3–5 members	188	59	51	8	239
6–15 members	131	41	96	15	227
16–19 members	—	—	170	27	170
More than 20 members	—	—	319	50	319
Total	319	100	636	100	955

TABLE 2

*Percentage of Patients Diagnosed by the General Staff In Three Group Practice Clinics as Having Psychiatric or Emotional Problems**

Group Plan	Type of Plan or Benefit	Population Characteristics	Total Number Screened	Percentage Diagnosed as Having Psychiatric or Emotional Problems
Group Health Association, Washington, D.C.	Prepaid group practice just prior to inclusion of psychiatric care benefits	Government employees, transit workers, general population	6,104	14.6
Jamaica Medical Group of Health Insurance Plan of Greater New York	(1965) Prepaid group practice program with free psychiatric consultation services only	Queens Borough in New York City. Lower-middle socioeconomic class; 25 percent black	**	4.2
	(1967) Prepaid group practice program with free psychiatric therapy included among benefits	Queens Borough	**	4.8
Field Clinic, Chicago, Illinois	Private group practice clinic. Fee-for-service paid directly by patient or through separate insurance plan	Middle socioeconomic class, predominantly German ethnic stock	500	15.0

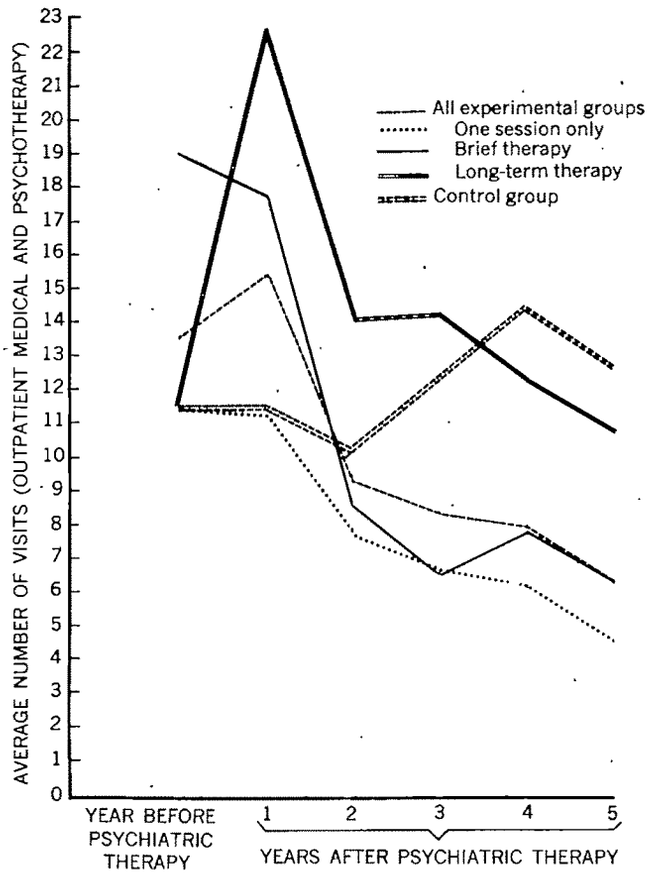
*Data based on various sources (6–9).

**Data not available.

services before and after the addition of psychiatric treatment at no cost to the patient in the Jamaica Medical Group of the Health Insurance Plan of Greater New York (HIP). In 1965, when the benefits consisted of only psychiatric consultation and diagnosis, the proportion of patients 15 years old and older who were given a psychiatric diagnosis was 4.2 percent of all patients seen during the three-month period studied. With the addition of psychiatric treatment in 1967 at no cost to the patient, those diagnosed as having psychiatric problems remained relatively the same—approximately 4.8 percent.

Crawford (7) surveyed 500 consecutive patients who visited a private group-practice clinic. The physicians were requested to fill out questionnaires indicating whether their diagnoses were judged to be "organic" and/or "emotional" in origin. Additional information on decisions to refer, treatment, and use of drugs was also collected. This clinic differed from those of the previous studies in that payment was required in the form of fee-for-service either through a private insurance plan or direct payment by the patient. Of the 500 patients screened, approximately 15 percent were judged as having some form of emotional problem.

Jackson (1), in an early survey of the Palo Alto Clinic (1956), reported that although 92 percent of the clinic physicians estimated that between ten and 50 percent of their patients needed psychiatric help, only one referral was made per 1,000 patient visits. He further reported that this figure was "even more startling when it is combined with the fact that 60 percent of these patients are referred by 16 percent of the clinic staff" (1).



These statistics on the diagnosis of psychiatric problems are interesting, first, for their variation among the three groups, which ranges from 4.2 percent through 15 percent. This rate of variance refers only to patients who come to the clinics for treatment and not to an entire population of eligible persons under a prepaid plan or within a geographic area. Estimates of the incidence of mental illness among the general population range from a 23.4 percent "impairment rate" in the midtown Manhattan study (10) to 50 percent "currently suffering from psychiatric disorder" in the Stirling County study (11). Second, the estimates are lower than those projected in the general population studies. However, the problem of validity in epidemiological studies of mental illness has not as yet been satisfactorily solved, and there is not an adequate baseline for comparison (12, 13). Whether or not the data indicate that a large proportion of psychiatric problems are not recognized or diagnosed is an area for further investigation; however, this has been the general opinion.

PATTERNS OF REFERRAL

The patterns of psychiatric referral by group physicians were investigated by two groups. In the GHA study (8) it was indicated that only 17 percent of those diagnosed as presenting psychiatric problems were referred for therapy, mostly to psychiatrists. However, the physicians reported that there was another 18 percent for whom they made no referral, although they felt that this group needed additional psychiatric treatment. The major reason given by the physicians for nonreferral was that they felt it would not be acceptable to the patient. Another reason they thought important was that referral was not feasible, mainly for financial reasons.

The HIP study (9) surveyed referral patterns when

FIGURE 2
*Average Number of Combined Medical and Psychiatric Outpatient Visits for Experimental and Control Groups**

*These data were adapted from Follette and Cummings (14).

only consultation and diagnostic services were available (1965) and after psychiatric therapy had also been offered (1967). Of those diagnosed as having psychiatric problems, the number referred to psychiatrists was also low in this study, but there was a small increase—from 22 percent in 1965 to 26 percent in 1967. A high percentage of patients (68 and 67 percent) were not referred to the clinic staff psychiatrist for various reasons. The family physician treated a large proportion of these. In some cases he was still in the process of diagnosing the patient at the time of the survey; other patients were judged not seriously ill enough for special treatment or were already in psychiatric treatment elsewhere. Ten percent of the cases in 1965 and seven percent in 1967 had doctor-patient discussions about the possibility of a referral, but no referral was made because of the patient's refusal to see a psychiatrist.

Of the patients who were referred for psychiatric treatment, both studies found that some of them rejected the referral. Of those referred to psychiatrists in the HIP study, this figure ranged from nine percent in 1965 to 14 percent in 1967. In the GHA study the psychiatrists selected about 50 percent of the referrals for psychiatric treatment and found that 35 percent of this group rejected psychiatric care.

Both studies found that general physicians spent considerable time discussing emotional problems with their patients diagnosed as having psychiatric problems. The GHA study reported that about 63 percent of this group received counseling. The rate was even higher in the HIP study. Family physicians reported having one or more discussions with 88 percent of the patients diagnosed as having psychiatric problems during the 1965 period, with a decrease to 76 percent in 1967 after therapy was made available.

The general physicians also prescribed psychotropic drugs to a large proportion of patients with emotional problems. In the GHA study prescriptions were written for 75 percent of this group. The HIP study reported rates of 78 percent in 1965 and of 79 percent in 1967.

In the two periods investigated, however, the HIP study found an increased tendency to refer to psychiatrists: 1) patients with conditions described as "less serious," 2) a wider range of emotional conditions, and 3) patients with problems judged likely to improve with professional care. In addition, the range of drugs prescribed increased, and the number and duration of discussions concerning psychiatric problems with patients decreased with the addition of psychiatric therapy services. A significant finding of this study was the increase in the psychiatric consultation rate (those referred to the psychiatrist for consultation but not treatment) from 7.0 per 1,000 eligible patients in 1965 to 11.0 per 1,000 in 1967. In 1969, when the demonstration project was discontinued, the consultation rate dropped back to 7.8 per 1,000, which is rather low.

UTILIZATION OF MEDICAL SERVICES

There have been three studies (Kaiser Foundation, GHA of Washington, D.C., and HIP of New York City) relating utilization of nonpsychiatric services before and after the introduction of short- or long-term psychiatric services as a prepaid benefit in a group medical setting. The methodology of all three studies was based upon a before-and-after census of utilization of physician and ancillary (X-ray and laboratory) services after psychiatric referral or service. We attempted a tabulation comparing the findings of these studies but did not find it to be appropriate since the studies differ in their definition of psychiatric care, follow-up time, population sampling, and rating scales.

Kaiser Foundation Plan

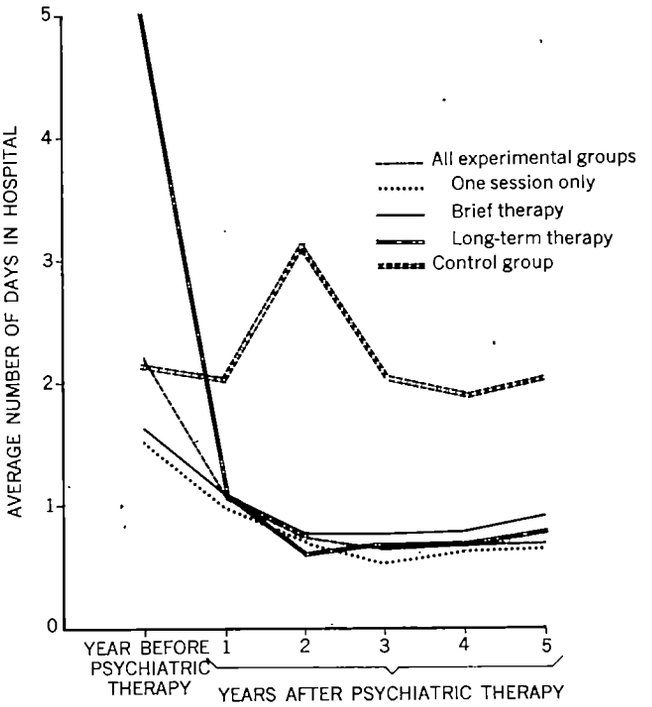
The Kaiser Foundation Plan (14) in northern California studied outpatient and inpatient medical care and psychiatric service utilization of three groups of psychotherapy patients. Every fifth psychiatric patient was an experimental subject, a total of 152 patients selected over a one-year period. The patients were stratified into three groups by the number of sessions they had a year: one interview only, brief therapy (mean of 6.2 interviews),

and long-term therapy (mean of 33.9 interviews). Each patient's utilization of health facilities was investigated first for the full year preceding the day of his initial interview and then for each of the succeeding five years beginning with the day after his interview. A control (nontherapy) group was selected for the corresponding years of the study, and utilization scores were based upon the total number of separate outpatient contacts and days of hospitalization.

The results of the Kaiser study indicated a great decline in medical utilization for the experimental group when compared with the control group, whose utilization increased slightly over the six years. This decline was apparent whether the measures used were the number of outpatient visits, days of hospitalization, or a combination of these with psychotherapy services.

Figure 2 illustrates the numbers in the three experimental subgroups who received outpatient care, expressed as averages for each subgroup combining medical and psychiatric visits. For the single-interview and brief psychotherapy groups the greatest decline in use was during the second year of therapy, followed by slight but continuous declines over the remaining years of the study. For these brief therapy groups the psychiatric visits surprisingly never quantitatively replaced or exceeded the number of outpatient visits made before psychotherapy. The long-term psychotherapy group also showed the greatest decline in use of services during the second year of therapy, followed by a leveling off and again a slight decline. In contrast with the brief psychotherapy patients the number of visits by long-term therapy patients after the first year of therapy either never decreased significantly from or slightly exceeded the number of visits before psychotherapy. These, of course, were probably higher risk patients, and this figure combines all outpatient visits, medical and psychiatric.

Inpatient care (days of hospitalization) showed steep declines for all experimental groups during the first year of therapy, followed by continuing but less severe declines in the second year and then a leveling off (see figure 3). For the one-session and brief psychotherapy groups there is a 60-percent decline in hospitalization between the year before and second year of therapy (significant at the .01 level). The decline in utilization is most dramatic for the long-term therapy group; it dropped approximately 88 percent from the year before therapy to the second year after therapy (significant at the .01 level). There was no significant difference in hospital utilization for the control group over the five years studied.



Group Health Association

The Group Health Association study (6) was limited to utilization of laboratory, X-ray, and nonpsychiatric services before and after each patient was referred for short-term psychiatric therapy over a period of two years. Data regarding the number of patients seen and the number of visits made were obtained on 256 patients.

The GHA study found that in the year after psychiatric referral there was a 13.6 percent reduction in the number of experimental-group patients who utilized the services

FIGURE 3

*Average Number of Days of Hospitalization for Experimental and Control Groups**

*These data were adapted from Follette and Cummings (14).

of nonpsychiatric departments; there was also a 15.7 percent reduction in the number who used laboratory or X-ray services. Over the same period the number of visits decreased by about 30 percent both for physician services and for laboratory or X-ray procedures. When the patients were analyzed according to age, race, sex, psychiatric diagnosis, and length of therapy, a consistent pattern of reduced utilization was observed. In comparison, data on the use of all GHA medical, laboratory, and X-ray services for the total population showed a per capita increase for the years 1963–1966.

Health Insurance Plan of Greater New York

The Health Insurance Plan of Greater New York (9), in an unpublished report to the National Institute of Mental Health, reported "some tendencies pointing to lower medical utilization in the group [of patients] to whom psychotherapy was available." The HIP study was a demonstration project that focused primarily on referral, utilization of psychiatric services, and staffing patterns of a mental health service in a prepaid group practice program. Because of methodological considerations, the investigators regarded that portion of the study on utilization of general medical services as "exploratory only."

In summary, these three studies found that short-term psychiatric care was associated with decreased utilization as measured by: 1) the number of patients requesting lab-

oratory, X-ray, and nonpsychiatric medical services, and 2) the number of patient visits for those services. In addition, the Kaiser Foundation Study demonstrated that for all of the psychiatric patients in their experimental group there was a decline in the number of visits even when both medical and psychiatric visits were combined. Of even greater significance is their demonstration of a dramatic decline in inpatient care. The consistency of these findings raises important questions concerning the nature and quantity of health care utilization.

Thus, the availability of psychiatric care on an equal basis with other treatment modalities seems not to increase expenses, as many fear, but to lessen overutilization of related services and inefficient use of highly trained practitioners. These findings merit more intensive investigation for their significance in planning services, particularly psychiatric coverage in health maintenance organizations and other medical care plans. Yet, regarding the five major national health insurance proposals currently before Congress, Gibson reported a tendency to keep mental health benefits minimal (15).

DISCUSSION

Over the past decade the number of medical groups in the United States has increased by a factor of four, currently involving over 40,000 nonfederal physicians. These provide a setting for continuing, comprehensive care that has the potential for minimizing fragmentation of services inherent in specialization.

Of all the major specialties, psychiatry was found to have the lowest number of members participating in groups. Investigations of diagnostic and referral patterns in group practice have been rather disheartening due to the low number of psychiatric patients diagnosed by general physicians and the small number referred to psychiatrists. Concurrently, the data in all three groups studied indicated that short-term psychiatric care was associated with a significant decrease in the utilization of other medical services. One study found an overall decline in the use of combined medical, psychiatric, laboratory, and X-ray services.

Other advantages of group practice have been documented. It increases the opportunity for contact between psychiatrists and other physicians who are an important primary contact in a patient's move toward psychotherapy. The notion of a "filter-down" process (16) begins with the patient's use of a family physician, the latter's diagnosis of a psychiatric condition, and referral to a psychiatrist. Goldensohn and associates (17) found that in group medical practice the family physician tended to refer more patients from population groups not otherwise likely to reach the psychiatrist in a system based upon self-referrals alone. These include the less educated and lower socioeconomic classes, those who hold less positive views of psychiatry, and those with emotional problems that they judge not to interfere severely with their life situation.

Some of the dynamics underlying the relationship of psychiatrists in group practice have been explored by Jackson (1) and Follette and Cummings (14). Both refer to the ambivalent position of psychiatry in relation to the rest of medicine. Goldensohn and associates, however, reported positive results in an expanded program of education and communication with family physicians (17). Jackson further observed that the "younger doctors differed significantly from their older colleagues in attitude toward psychiatry and the percentage of patients [they saw] needing help."

Clearly, there are advantages in systems that minimize fragmentation of services, open up communication among specialists, and reduce overall utilization rates. As we tend to move toward group practice as a major organizational form for the delivery of health care, it is important to understand the role of the psychiatrist in such a setting, his relationship to his peers, and his significance in the medical care equation. In summary, psychiatric services tend to keep down the overall costs of medical care and, in large group settings that are characterized by efficiency and anonymity, to contribute a humanistic aspect to medical practice.

A Year's Experience in Student Mental Health at West Point

BY RICHARD C. U'REN, M.D., LT. COL. FRANCIS E. CONRAD, MC, USA, AND COL. PETER H. PATTERSON, MC, USA

A one-year study at West Point revealed that most cadets seen in the mental hygiene service did not have symptoms indicative of a major psychiatric illness; many were diagnosed as having adjustment reactions. Similar findings have been reported among students at civilian institutions. However, the cadets had lower rates of self-referrals and diagnoses of personality disorder and higher frequencies of suicide gestures and psychophysiological reactions.

THE U.S. MILITARY ACADEMY was the first college or university in the United States to have a full-time student health psychiatrist. Harry Kerns was appointed to West Point in 1920 and reported on his experience there a short time later (1). Since that time there has been a lack of information about student mental health not only at West Point, but at the other military service academies as well. This paper describes activities in the Military Academy's Mental Hygiene Consultation Service during the 1970–1971 academic year (half a century after Kerns was appointed) and illustrates some of the important differences between mental health operations at the Military Academy and at other educational institutions.

Between July 1, 1970, and June 30, 1971, the enrollment at West Point was approximately 3,780. Of this number 1,375 were new cadets (freshmen or first-year men), who arrived on the first day of July for two months of rigorous physical and military training prior to the beginning of the academic year in September. This two-month period is also a time of rapid assimilation into the culture of the Military Academy. The responsibility for this program is borne by upperclassmen, who are closely supervised by a group of selected Army officers called tactical officers. This period, called New Cadet Barracks, is a particularly stressful part of the West Point experience.

Cadets who wish counseling services have a choice of several facilities on post: the Mental Hygiene Consultation Service, which is located in the hospital; the Counseling Office, which is located in the barracks area; and the Protestant and Catholic chaplains' offices. Although cadets may seek help directly from the Mental Hygiene Consultation Service, they have been encouraged in the past to talk first to their tactical officers who, in turn, may refer the cadet to one of the counseling facilities.

Frequently, the tactical officer will choose to refer the cadet to the Counseling Office, which is staffed by regular Army officers with graduate degrees in psychology or counseling. A subsequent referral may be made to the Mental Hygiene Service if additional evaluation, treatment, or hospitalization is thought to be necessary. The Counseling Office, in addition to its counseling duties, routinely interviews all resignees from the Academy. In the past year the Counseling Office interviewed 576 men; approximately half were seen for routine resignation interviews, and the rest were counseled for a variety of reasons. Of these, eight percent were self-referred and 2.4 percent required referral to the Mental Hygiene Service.

The Protestant chaplain's office counseled approximately 70 cadets during the year, only one of whom was referred to the Mental Hygiene Service. There are, of course, others to whom a cadet may go for advice and counseling in less formal ways; his tactical officer and other officers, the cadet hostess, and the Catholic chaplain are among those commonly used.

The Mental Hygiene Consultation Service, which has steadily expanded in the past year, is now staffed by two psychiatrists, one psychologist, one social worker, and two psychology/social work specialists. This unit serves the entire West Point community; only 21.4 percent of the new patients seen in the 1970–1971 year were cadets. Table 1 gives a brief summary of the operations of the Mental Hygiene Consultation Service during the 1970–1971 year. There was a total of 2,525 outpatient visits and an average of 4.6 interviews per patient. Excluding cadets, 30 people (6.9 percent) were hospitalized.

This paper focuses exclusively on the cadet population.

DIAGNOSTIC BREAKDOWN AND SOME COMPARISONS

Table 2 shows the breakdown, by diagnosis, of the 119 cadets seen from July 1, 1970, to June 30, 1971, in the Mental Hygiene Consultation Service.

Table 3 illustrates how diagnoses at West Point compared with diagnoses reported in the literature from other student mental hygiene units (2, 3).

For several reasons it is difficult to compare diagnoses from one facility to another. First, there are idiosyncrasies in diagnosis specific to individual clinics. Second, a majority of the reports from other mental hygiene consultation units are based on a coeducational population; West Point, thus far, enrolls only men. Third, graduate

At the time this work was done, the authors were all with the U.S. Army Hospital, U.S. Military Academy, West Point, N.Y., where Dr. U'Ren, a former Major in the Medical Corps, was Chief of the Mental Hygiene Consultation Service, Lt. Col. Conrad is currently Chief of that Service, and Col. Patterson is Chief of Professional Services. Dr. U'Ren is now Director, Psychiatry Outpatient Clinic, University of Oregon Medical School, Portland, Ore. 97201.

TABLE 1
Mental Hygiene Consultation Service Operations: July 1, 1970–June 30, 1971

Classification of New Patients	Number = 555	Percentage of Total	Usage Rate per 1,000
Active-duty personnel	182	32.9	82.0
Enlisted men and women	159	28.6	114.0
Officers	23	4.3	28.2
Active-duty dependents	158	28.4	35.4
Cadets	119	21.4	31.7
Retired personnel and dependents	96	17.3	—

students are included in statistics reported by most facilities, and there is evidence that they are overrepresented in the clinic population (3, 4).

Nevertheless, tables 2 and 3 are instructive. For a variety of reasons adjustment reaction of adolescence was diagnosed frequently. According to the second edition of the *Diagnostic and Statistical Manual of Mental Disorders* (5), the main criteria for this diagnosis are the following: 1) there is an absence of serious underlying mental disorder; 2) symptoms represent a response to overwhelming stress; and 3) symptoms disappear as the stress diminishes.

The frequency of this diagnosis reflects a generally high level of adaptability among cadets. West Point tends to attract young men who are upwardly mobile, "who have to depend upon their merits to achieve success, and who ... have *already* met the challenge of academic work, peer group relations, and athletic competition" (italics added) (6). There is a great deal of preselection in application to West Point. Adolescents who are introverted and nonathletic would probably not apply to any of the service academies. Furthermore, in situations where questions arose with regard to classification, the less prejudicial diagnosis was chosen, since psychiatric reports may end up in a cadet's personal file.[1] Anxiety as a clinical phenomenon was, therefore, almost always classified as an adjustment reaction rather than as a neurosis. The frequency of this diagnosis, however, is not surprising in an environment as stressful as West Point. Many times, in fact, the following statements were made in the diagnostic paragraph in order to underline this conservative attitude toward diagnosis:

1. "No psychological illness."
2. "Adjustment reaction of adolescence as manifested by ...."

From table 3 one can see that the diagnosis of adjustment reaction/transient situational reaction of adolescence is also made frequently in other mental hygiene clinics. At West Point, as at civilian colleges, the incidence of serious psychiatric disorders, e.g., psychoses, is very low.

Table 2 does reflect the existence of early stresses at West Point. Eleven suicide gestures among 1,375 new cadets (eight per 1,000) in a two-month period is high. We were often reluctant to call many of the minor gestures

TABLE 2
Diagnostic Breakdown of Cadets Seen in the Mental Hygiene Consultation Service: July 1, 1970–June 30, 1971

***Four suicides per 15,000 student body (1969–1970) (20).

we saw "suicide" gestures.[2] During July and August not one cadet was seen who seriously wanted to take his own life. Rather, a suicide gesture was a deliberate act made by a cadet who felt that his request to resign from the Academy was being ignored. Nonetheless, all suicide gestures were taken seriously regardless of conjecture about motivation. Ten of these 11 men resigned from the Academy before the end of the summer. Through communications with psychiatrists previously stationed at West Point, we learned that only one cadet has successfully completed suicide since July 1965. This particular man was away from the Academy when he killed himself, and he had not previously come to the attention of the Mental Hygiene Consultation Service. We estimate that there have been 49 suicide gestures at West Point since July 1965. In that time, the Corps of Cadets (the student body) has expanded from approximately 2,700 to 3,700 men.

Three cadets were diagnosed as having conversion reactions. The first had an amblyopia associated with a religious conflict; he regained his sight in the affected eye four months after leaving the Academy. The second had a temporary aphonia and later resigned. The third, who remained at West Point, had a leg paralysis that lasted only a short time.

The frequency of psychophysiological reactions was high (tables 2 and 3), and two-thirds of them occurred during July and August. It has become axiomatic that if a cadet remains a week in the hospital (on the medical service) with persistent gastrointestinal symptoms and no demonstrable etiology, he has a conflict about being at West Point. Kerns, in 1923, put it this way:

> No system can take a group of young men, dress them alike, teach them alike, drill them alike, and grind them through the same machine, without breaking a few of them. Fortunately conditions for observation and general supervision of cases could hardly be better. The medical department is the one flexible link in the military chain; the doctor is custodian of the keys that open the door to escape; the hospital is the safety valve.... The schedule is so rigorous that the cadet is only too glad to consult the physician upon the slightest pretext, in the hope that he may be excused from drill or be admitted to the hospital for a few days' rest (10, p. 690).

As evidence that the Medical Department is still used as a flexible link, approximately 3,780 cadets made 15,120 visits to sick call during the 1970–1971 year. Oc-

[2] Statistics documenting the ratio of attempted suicides to completed suicides among men aged 17 to 23 are hard to find. Among adolescents this ratio has been estimated to be from 7:1 (8) to 50:1 (9). It is difficult to understand why statistics on suicide gestures and suicides are not included in reports from the larger mental hygiene facilities (2, 3).

TABLE 5
Comparison of Referral Sources to Student Mental Health Units

West Point (One-Year Period, N=119)		University of Illinois (Ten-Year Period, N=4,547 [3])		Indiana University (One-Year Period, N=647 [2])	
Referral Source	Percentage of Total*	Referral Source	Percentage of Total*	Referral Source	Percentage of Total*
Health service physicians and emergency room	58.8	Self	43.1	Self	41.0
Self	13.5	Health service physicians	26.8	Health service physicians	21.7

Other	2.4	Another student	4.6	Former or current patients	<5.0
		Outside physician	4.5	Residence hall counselors	<5.0

*Percentages do not total 100 percent because only the most common referral sources are listed.

casionally, 100 to 120 cadets were seen in a single day.

As mentioned earlier, the first two months of each academic year are a period of great stress for new cadets. The purpose of this early training is to assimilate new students into the culture and traditions of the Academy.[3] The main stresses are the loss of previous status, autonomy, and individuality; the rigorous physical and military training; the separation from family and familiar peer groups; and the disciplinary system. This process is similar to basic training (12).

In addition to the high resignation rate among cadets during this time—3.5 percent to 9.5 percent of the entering class—other stresses are reflected in Mental Hygiene Consultation Service statistics. During the first two months of the 1970–1971 year, the mental hygiene unit saw 31 percent of all cadets interviewed for psychiatric reasons during the year, 33 percent of all the adjustment reactions, 67 percent of the psychophysiological disorders, and 73 percent of all suicide gestures that occurred during the year. In addition, 45 percent of all cadet hospitalizations associated with psychiatric difficulties occurred during this time,[4] and there were no self-referrals to the unit during that time. The rate of diagnosed personality disorders is extremely low compared to civilian mental hygiene units. In most series, the common personality diagnoses are passive-aggressive (2) or schizoid (3, 13). The preselection factor has already been mentioned and, to quote Kerns again: "For the artistic type at West Point the way is hard. The monotony and grind of military precision, and the total lack of opportunity for individual expression, are most harrowing to the sensitive, fine-grained, imaginative lads" (14, p. 274).

[3] For an excellent article on this process, see Dornbush's article "The Military Academy as an Assimilating Institution" (11).

[4] Many of the hospitalizations were initiated by other physicians, particularly internists and surgeons, who then consulted the psychiatric service when they suspected that their patients might have a psychological problem. Forty-nine of the 119 patients seen by Mental Hygiene Consultation Service personnel were either hospitalized or seen as hospitalized patients on other medical services.

Of the total number of cadets seen in the mental hygiene unit, 6.8 percent were referred for evaluations. Two cadets were seen for allegedly smoking marijuana. Neither had a psychological problem. There has been experimentation with marijuana among cadets at West Point, just as there has been at other service academies (15, 16). No one is sure of the extent of its use at West Point.

Four cadets sought help for sexual problems. Diagnoses here included premature ejaculation, impotence, and concern about homosexuality. All of this group were self-referrals. Five cadets came for advice about specific situational problems, and 11 others, who were referred for various reasons such as academic problems, did not warrant a psychiatric diagnosis. The incidence of psychosis is lower at West Point than at civilian colleges. A comparison of statistics at several mental hygiene units (3, 17–20), including West Point's, is shown in table 4.

REFERRAL SOURCES AND USAGE RATES

Table 5 shows the referral sources to the Mental Hygiene Consultation Service for the 1970–1971 year.

Only 13.5 percent of the cadets seen in the mental hygiene unit were self-referred. This figure contrasts with figures from other universities where the percentage of self-referrals ranges from 41 percent (3) to 43 percent (7). There are several factors involved. The military is still generally considered to be a conservative establishment;

TABLE 6
Cadets Seen in the Mental Hygiene Consultation Service by Class: July 1, 1970–June 30, 1971

Class	Number	Percentage of Total
Freshman	74	62.2
Sophomore	24	20.1
Junior	12	10.1
Senior	9	7.6

seeking help from others, especially psychiatrists, is not yet part of the military ethic. Cadets are concerned that a visit to the mental hygiene unit will appear on their record. Those cadets who were referred were told that the Mental Hygiene Consultation Service would have to share its impressions with the referring source. There have been no instances where confidentiality has been breached with cadets who were self-referred. Such a possibility exists, however, under the present system.

In view of these factors, it is difficult to estimate the true prevalence of psychiatric illness at West Point. The usage rate derived from *both* the Counseling Office and the Mental Hygiene Consultation Service statistics (N = 261, excluding cadets seen only for resignation interviews) is 6.9 per 1,000 per year. Although cadets, for the reasons mentioned earlier, are reluctant to come to the Mental Hygiene Consultation Service, there is also the fact that they are closely monitored. In any situation where conformity is the rule, deviation from established and traditional norms quickly attracts attention.

The greatest number of students seen in our clinic came from the first-year class. This was also found to be true in Baker and Nidorf's study at Clark University (21), but not in the studies done at the Universities of Illinois (3) and Indiana (2), which showed that more students were drawn from the upper classes. Table 6 shows the breakdown, by class, of patients seen during the 1970–1971 year.

These figures are not surprising, since the first year is the most stressful of the four at West Point. Two of the three psychiatric discharges that were recommended during the year involved first-year cadets. In recent years the attrition rate at West Point over the four-year period has been about 30 percent. Eighteen percent occurs in the first year, seven percent in the second year, three percent in the third year, and less than one percent in the fourth. Nationally, 60 percent of all students who enter college will not graduate from the institution they first enter (17).

SUMMARY

In summary, there are similarities but also important differences between student mental health at West Point and at civilian institutions. The similarities are as follows. A majority of students did not have symptoms that indicated a major psychiatric illness; many students were diagnosed as having adjustment reactions; and the average number of interviews per student was close to the national average. The usage rate at West Point is lower than the national average but is higher than at least one other large university (see table 4).

The most significant differences are the low rate of self-referrals, the high frequency of suicide gestures (but low completion rate), the high number of psychophysiological reactions, and the low prevalence of personality disorder diagnoses.

Psychiatric Factors in Security Screening

BY LOUIS LINN, M.D.

In screening an individual for a security clearance, there are two possible categories of mental disorder: one requiring an adverse opinion and the other a favorable opinion in spite of the presence of such a disorder. In this study of 85 evaluations, symptoms not associated with acting out such as anxiety, depression, and psychosomatic disorders were rarely a basis for an adverse opinion. Nor did hospitalization, electroshock therapy, or prolonged intensive psychotherapy in themselves constitute a basis for an adverse opinion. The author points out that the psychiatric factor is but a single element in the overall determination of eligibility to have access to classified information.

FROM TIME TO TIME an employee with access to classified information of the Department of Defense commits a security lapse as a consequence of mental disorder.

In one example, an overworked and overly conscientious engineer was seized by the belief that he was about to make inappropriate disclosures. In a panic he checked into a nearby motel, left his dispatch case in a dresser drawer, locked his room behind him, and fled. Several days later, confused and amnesic, he was admitted to a municipal hospital hundreds of miles from home. In the meantime the motel owner had discovered the abandoned dispatch case and had turned it over to the FBI when he discerned the official nature of its contents.

In another instance a technician in an airplane factory became acutely psychotic and had to be hospitalized after a drinking bout in a local bar. His delusional system contained many references to classified information in a defense contract.

To forestall security lapses the Industrial Personnel Security Program was established to make final determinations of the security qualifications of individuals employed by private contractors whose work requires access to classified information of the Department of Defense and other federal agencies.

The Department of Defense directive setting forth the criteria for issuing security clearance (1) lists 21 separate items that may provide a basis for rejection. These largely involve questionable political and ideological affiliations, as well as evidence of outright seditious activity. Needless to say, these issues are not relevant to the skills of the psychiatrist. In fact, only one criterion for rejection pertains specifically to psychiatry. This criterion includes:

> Any illness, including any mental condition of a nature which in the opinion of competent medical authority may cause significant defect in the judgment or reliability of the employee, with due regard to the transient or continuing effect of the illness and the medical findings in such case (1).

It is on the basis of this explicit and sharply circumscribed medical provision that the Department of Defense enlists psychiatric consultation to help resolve two basic questions: 1) Does there exist in the subject any illness or mental condition that might cause a significant defect in his judgment or reliability, specifically with respect to his ability to safeguard classified information? and 2) If the subject is in remission at the time of the examination, what is the likelihood that he may suffer a recurrence that will impair his ability to safeguard classified information in the future?

The Department of Defense directive defines the issue even more explicitly. It assumes, in effect, the actual existence of some defect in judgment and reliability due to mental disorder. Does such a disorder also impair the subject's ability to safeguard classified information, or is the defect a limited one that will not adversely affect his ability in this regard? These questions imply that, from the viewpoint of security clearance, there are two distinct categories of mental disorder: one that calls for an adverse opinion, another that suggests acceptance for clearance in spite of the presence of mental disorder.

It is easy to conceptualize certain diagnostic entities such as a simple depressive reaction or psychosomatic symptom formation in which impairment of one's judgment, if present at all, is highly circumscribed. On the other hand, there are other individuals who are potentially dangerous from a security point of view because they are prone to irrational social interactions. Thus the Department of Defense is not concerned with diagnosis per se, with a history of hospitalization, or with the nature of previous psychiatric treatment. It is prepared to disregard these or, indeed, any psychiatric data that, in the opinion of the consultant, do not impair the subject's capacity to safeguard classified information now and in the future.

If the mental disorder in question is clearly present at the time of the evaluation, the problem is relatively simple. However, the mental condition is very often in remission at this time and as a consequence the subject

Read at the 125th annual meeting of the American Psychiatric Association, Dallas, Tex., May 1–5, 1972.

Dr. Linn is Clinical Professor of Psychiatry, Mount Sinai School of Medicine, City University of New York, New York, N.Y. His address is 9 East 96th St., New York, N.Y. 10028.

shows no overt psychopathology. In these instances the determination depends to a considerable degree on the reconstruction of past events, as well as on direct examination. If the request for a psychiatric examination is based on an episode of mental illness that occurred many years previously, the consultant must take into account the effects of maturation and emotional growth in assessing the likelihood of recurrence in the future and its possible nature.

Furthermore, the consultant knows that an adverse opinion may mean the loss of the subject's job and may affect his future vocational prospects. This responsibility weighs heavily on him and, understandably, may incline him to equivocate and recommend a "provisional" security clearance in certain marginal instances. However, the subject thus evaluated may be promoted at any time to a more responsible position with greater emotional pressure or to a more security-sensitive post. The problem of reevaluating such marginal subjects with each job change would be too formidable, and so the Department of Defense asks the consultant to make a definitive recommendation for or against security clearance with respect to every subject he examines.

Obviously, the clinical psychiatric problem is not a simple one, and it seemed timely to initiate a dialogue on this topic. Accordingly, a systematic analysis of our reports was undertaken to determine the way in which my efforts to fulfill the Department of Defense directive took shape. The following summary of my experiences is to help similarly involved colleagues to sharpen basic concepts, improve techniques, and share experiences with new or future consultants.

METHOD

From 1966–1971, I saw in consultation 85 selected subjects, all of whom volunteered, on Department of Defense inquiry, that they had received a psychiatric diagnosis at some earlier time. My task was to evaluate this previously made diagnosis and to decide if the associated clinical facts warranted an opinion in favor of disqualification.

The department places at the consultant's disposal a file of previous hospital and legal records, reports of prior interviews with physicians (all data are furnished with the subject's consent), and the individual's responses to the Personnel Security Questionnaire (1). Although a consultant may repeatedly interview the subject and may arrange for psychological testing, this study is almost entirely the result of single interviews and used no additional psychological data beyond those already present in the files. A total of six subjects had been previously tested.

I reviewed my consultation reports and decided on 74 items for special scrutiny in the context of a retrospective study. A coding system was devised for transposing these items to punchcards for analysis by a sorting machine. Aside from basic demographic data, I focused on the following additional items: 1) the nature and locale of previous treatment, 2) symptom inventory, 3) acting-out tendencies, 4) diagnosis, 5) evidence of falsification in previous records, 6) pathological behavior manifested to the examiner, 7) evidence of insight, 8) evidence of emotional growth, and 9) comparison of previous diagnoses with the current diagnosis.

TABLE 1
Percentage of Those Rejected by Age Groups

Age Group	Total Number	Percentage Rejected
19–29 years	46	22
30–39 years	20	30
40–49 years	14	36
50 years and older	5	40
Total	85	27

RESULTS

Of the 85 evaluations made, 23 (27 percent) resulted in adverse opinions for security clearance on psychiatric grounds (designated hereafter as "rejection"). The remaining 62 (73 percent) were judged suitable for clearance and the opinion was for acceptance.

There is a tendency for the rate of rejection to increase at older age levels, probably reflecting an unstable work history, particularly in those in their 40s and 50s who are applying for security clearance for new jobs (see table 1).

The rejection rate for men was three times that for women: 21 (30 percent) of a total of 68 men, compared with two (12 percent) of a total of 17 women. This probably reflects the greater propensity for acting out in males, as well as a greater tendency for depressive reactions in female subjects.

A history of inpatient treatment occurred in 17 (74 percent) of those rejected, compared with 37 (57 percent) of those accepted. This is not a great difference and reflects the fact that many subjects had periods of inpatient care for relatively benign disorders while serving in the military.

Of 23 subjects who manifested psychopathology (for example, inappropriate affect, thought disorders, or psychomotor abnormalities) prior to the interview, that is when they were on the telephone making an appointment, in the waiting room, etc., 14 were rejected and nine were accepted.

Of all of the subjects who were rated rejected, 16 (70 percent) showed overt abnormalities in mental status at the time of examination, compared with 14 (20 percent) of those who were rated accepted. (See table 2.)

One subject among those rejected displayed assaultiveness and fire setting. This was not encountered among those accepted.

Acting-out behavior was seen among 21 (91 percent) of those rejected and 27 (43 percent) of those accepted. Of the 23 rejected, ten were diagnosed as schizophrenic,

TABLE 2
Overt Abnormalities of Accepted and Rejected Subjects

Abnormality	Accepted		Rejected	
	Number	Percent	Number	Percent
Delusions	3	5	12	52
Sexual deviation	5	8	6	26
Alcoholism	9	14	14	61
Other addiction	1	1	2	9
Police record	4	6	5	21
Antisocial behavior	12	19	8	35
Serious suicide attempt	3	4	2	9
Dissociative reaction	1	1	1	4

seven had personality disorders, and five were sexual deviates. It is noteworthy that alcoholism was a primary diagnosis in only one individual who was rejected, even though a history of alcohol abuse was present in 14 rejectees. Of the four subjects who falsified information on the Personnel Security Questionnaire, three were rated as rejected. The one who was accepted was an emotionally immature 20-year-old man who, as an extenuating circumstance, showed evidence of emotional growth in his recent life history.

In ten cases the information obtained from the subject during the office interview did not correspond to the information in the subject's files. In each case the subject claimed amnesia for the evidence in question; nine (90 percent) of these ten were rejected and one (one percent) was accepted.

In discussing a previous episode of mental disorder, 17 subjects evinced no insight concerning the nature of that illness; 13 (60 percent) of these were rated rejected and four (six percent) were rated accepted. Because the episode of mental disorder in question occasionally preceded my performing the psychiatric examination by several years, an attempt was made to estimate evidence of emotional growth, i.e., improvement in the quality of object relationships in the interim period with respect to: 1) family, 2) work, 3) social life, and 4) life in the community. When present, such evidence of growth and maturation weighed significantly in the examiner's recommendation for clearance. Those accepted scored positively for improvement as follows: 90, 80, 70, and 60 percent, respectively for each of the foregoing areas; by contrast, those rejected scored positively as 30, 30, 4, and 8 percent, respectively, for each of the categories.

This study provided a unique opportunity for a long-term follow-up of individuals who had suffered episodes of mental illness, some of considerable severity, earlier in life. It was impressive to observe how often subjects had been able to recover from acute episodes and to continue the process of maturation and emotional growth. The breakdown had frequently occurred during a period of chronological immaturity, such as during adolescence or early adulthood. Psychiatric treatment that enabled the individual to achieve constructive insights and changes in his life circumstances such as further education, a stable job situation, a congenial marriage, and a benign social setting counted heavily toward a positive opinion despite a history of previous severe psychopathology.

In 21 cases in which individuals had been previously rejected my diagnoses agreed with those previously noted in the file. On the other hand, there were 18 cases of individuals who had previously been accepted in which the initial diagnosis was changed. A retrospective evaluation of this group suggested revision to a more benign diagnosis. For example, certain subjects who were clearly not psychotic at the time of my evaluation had a history of emotional disorder limited to the military and diagnosed as schizophrenia at that time. A reconsideration of the facts and the subsequent clinical course suggested changing this diagnosis to adjustment reaction of adult life to reflect the consultant's opinion that the mental disorder in question was relatively benign and that any associated judgment impairment was probably not significant from a security point of view.

In more general terms, subjects in whom the preceding episode of mental disorder had been limited to clear-cut evidence of exceptional environmental stress were more likely to be among those recommended for clearance. While this phenomenon was observed particularly among subjects whose illness was limited to the military, it was also observed in others who were, for example, undergoing marital separation, long intervals of working overtime, or serious physical illness in close family members.

Many subjects had a history of severe depressive episodes necessitating hospitalization and electroshock therapy or anxiety states or psychosomatic disorders requiring medication and psychotherapy. In each of these instances the psychiatric history was not considered disqualifying. On the contrary, evidences of emotional growth as a consequence of successful treatment were in at least a few cases a basis for recommending clearance in spite of serious psychopathology in the past.

However, psychopathology was regarded as a potential source of danger from a security clearance point of view if it was associated with specific abnormal behavior patterns impinging on society at large. For example, any behavior leading to public disturbance with legal entanglements and publicity as a consequence of delusions, hallucinations, or compulsive deviant sexual behavior was regarded as disqualifying.

Educational background and job skills were represented at all levels without significant trends toward favorable or adverse opinions. A history of vocational instability occurred in 13 (60 percent) of those rejected and in one (one percent) of those accepted.

APPEALS PROCEDURE

I participated in several hearings initiated by subjects to review an adverse decision concerning security clearance and was impressed by the respect and fairness the Department of Defense showed the subject during the hearings and particularly by the opportunities for appeal.

The consultant's role is a purely advisory one. If he recommends clearance, his opinion is rarely questioned, particularly if his rationale is clearly spelled out. On the other hand, in the event that the consultant's opinion is adverse and the subject is rejected for security clearance, the subject is notified that he may contest this decision. Should he choose to do so, he can be represented by counsel, and the entire matter is intensively scrutinized before a hearing examiner who conducts a hearing in the Department of Defense local field board office, where the consultant is required to testify on the nature of his findings. In giving testimony the consultant presents his evaluation and must defend it under cross-examination in much the same manner as in a court of law. Any determination by a hearing examiner may be appealed to the Appeal Board in the Pentagon. Notwithstanding the basic fairness of the procedure, it should be pointed out that the Department of Defense directive relating to mental disorder expressly calls for the opinion of "competent medical authority." It would seem consistent, therefore, to include appropriate medical consultation in the appeals procedure as well.

The Department of Defense relies almost exclusively on civilian consultants for its industrial defense contract clearances not only because this provides the largest possible pool of senior clinicians but also because, as independent practitioners, their decisions are made presumably with the greatest possible objectivity and on the basis of the same clinical judgments that prevail in private practice.

CONFIDENTIALITY

As to the issue of confidentiality, inasmuch as the consultant is retained by the Department of Defense he must submit his findings to that agency (2). The subject has this carefully explained to him at the start of the evaluation interview. Thus the subject participates in this procedure voluntarily. He does so because he wishes to work at a specific job requiring security clearance. In no way does this inquiry impugn his loyalty or his right to work in any other setting. Naturally, the consultant will protect the subject's disclosures in all other respects as with any person whom he sees professionally. Although the issue of national security is specifically involved, the principle at stake in these consultations is no different from that involved in many related situations. For example, a physician in an induction station may have to disqualify an individual on the basis of his findings no matter how eager the recruit may be to serve in the military. Or a physician may have to disqualify a highly deserving applicant for an insurance policy if his physical condition so indicates. In each of these situations the physician makes appropriate disclosures to the agency for which he is serving as consultant, with the knowledge and consent of the subject. Any other arrangement is unimaginable. Thus the issue of confidentiality is not unique or even unusual in this program and must, in any case, be distinguished from the situation that prevails in a therapeutic relationship between the physician and his patient.

PREDOMINANCE OF NONPSYCHIATRIC FACTORS

Finally, it is well to recall that the psychiatric basis for disqualification is only one of 21 items. Psychiatric opinions for disqualification have been essentially preventive in nature, that is, none of the subjects examined had ever committed a security breach. A retrospective study of individuals actually guilty of a security lapse from any cause would not only be informative but could place this entire process on a more scientific basis. It is my speculation that the majority of these lapses would involve individuals without overt mental illness and that the psychiatric factor would constitute at most a minor element in the overall picture compared to ideologic and political considerations.

SUMMARY AND CONCLUSIONS

There are two distinct categories of mental disorder from the point of view of security clearance: one that calls for an adverse opinion vis-à-vis security clearance and another in which the opinion for clearance is favorable in spite of mental disorder.

In this study 85 subjects requiring security clearance for access to classified information were examined because of a history of previous psychopathology. In 62 (73 percent) of the cases the opinion regarding clearance was favorable; in 23 (27 percent) the opinion was adverse.

Of those rejected, 21 (90 percent) showed a tendency to act out, that is, a tendency to translate pathological thoughts and feelings into behavioral terms. Other factors associated with a high percentage of rejection were age (highest in the 40s and 50s), sex (higher in men), falsification during the preliminary security investigation, job instability, and psychopathology manifested during this interviewer's examination. Diagnostically, schizophrenia, personality disorder, and sexual deviation were present in 20 of the 21 who were rejected. Although alcoholism was a primary diagnosis in only one instance, alcohol abuse was present in 14 (60 percent) of those who were refused a security clearance.

Symptoms *not* associated with acting out, such as anxiety, depression, and psychosomatic disorders, were rarely a basis for an adverse opinion. Hospitalization, electroshock therapy, or prolonged intensive psychotherapy did not, in themselves, constitute a basis for an adverse opinion.

This study provided a longitudinal view of many subjects. Evidence of emotional growth, with or without psychiatric help, counted heavily toward a favorable opinion despite a history of severe psychopathology in a few instances.

Regulations governing the rights of individuals under-

going evaluation seem to be administered with fairness and respect.

The psychiatric factor constitutes at most a single element in the overall problem of determining eligibility for security clearance and is probably a minor one in comparison with political and ideological considerations.

"Credentials Consciousness": Stimulus for Continuing Education and Peer Review in Psychiatry

BY DONALD H. NAFTULIN, M.D.

The author surveys various issues related to continuing education in psychiatry, including the delineation of "credentialing" as a stimulus to the kind of quality control that the health care system seems to be moving toward. He considers the patient-management approach to identifying professional competence the most effective means of implementing continuing education; this approach is relevant to peer review and effective delivery of mental health services.

CONTINUING EDUCATION in the health sciences may well be a euphemism for peer review and quality control of health care. Those who view this as an overstatement might consider the words of Heinz R. Kuehn, administrative associate of the American College of Surgeons: "Peer review has become one of the most effective methods of educating the physician and reviewing the quality of medical care" (1). Similarly, the Pennsylvania Medical Society's "Guidelines for Peer Review Activity" (2) recommends that the chairman of a departmental audit committee be one who "understands the educational potential for medical audit and who wishes to see it work in this [educational] way."

It is likely that many more than the current four states (Arizona, Ohio, Oregon, and Pennsylvania) will soon require demonstrable continuing education as a prerequisite for sustained medical society membership. And it is more than likely that the legislative proposal to make Medicaid payment to physicians contingent on demonstrable continuing education, although it has been defeated in the past, will be passed in future sessions of Congress (3). Comprehensive Health Planning monies, when funded, are partially earmarked for continuing education, and health maintenance organization (HMO) management training grants have been extended to encourage physician "trainees," a form of continuing education in this innovative concept of health care delivery (4).

The American Medical Association has mounted a volunteer program of continuing education accreditation for its members—but with limited success. Until New Mexico mandated continuing education accreditation as a condition for physician relicensure,[1] it was uncertain how concerned health professionals were about mandatory continuing education programs (5). The American Psychiatric Association, through its Office of Continuing Education, was among the first organized medical specialty groups to develop a self-assessment program to enhance physician knowledge and, it is hoped, skills (6).

On November 15, 1971, Governor Ronald Reagan of California signed into law Assembly Bill 449, proposed by Assemblyman Gordon Duffy, establishing a Council on Continuing Education for the Health Occupations; currently the measure is applicable only to registered and licensed vocational nurses (7). In essence, the law provides that the council establish standards for continuing education as a prerequisite for continued licensure in each of the fields it covers. It is unknown when the state legislature will amend the law to include other health professionals, but the trend is clear.

All these events are bringing continuing education and peer review much closer together. Organized medicine, and certainly organized psychiatry, will be confronted with the task of developing mandatory continuing education programs that are meaningful not just to the perceived needs of their members but the patient population those members serve. This is no easy task for any group, but perhaps it is especially difficult for psychiatry. Psychiatry's job is complicated not only by a lack of specificity in methods and outcome measures but also by the poor correlation between the numerous substantive advances in the sciences contributing to psychiatry and the day-to-day application of such contributions to patient care (8, p. 8). Phrased differently, one can ask whether the psychiatrist practitioner is sufficiently challenged by perplexing clinical problems and, if so, whether he feels that the impact of the medical information explosion can contribute to his therapeutic skills.

RELEVANCE OF SKILLS TO PSYCHIATRISTS' ACTIVITIES

When 1,600 psychiatrists in the southwest were sur-

Dr. Naftulin is Associate Professor of Psychiatry and Director of the Continuing Education Division, Department of Psychiatry, University of Southern California School of Medicine, 2025 Zonal Ave., Los Angeles, Calif. 90033.

This work was supported in part by Public Health Service grant MH-10886 from the National Institute of Mental Health.

The author would like to thank Dr. George H. Wolkon for his criticism of this paper.

[1] Although it is a requirement for physician relicensure in New Mexico, continuing education is not a requirement for sustained medical society membership.

veyed as to how often they were called upon to engage in an activity for which they felt ill prepared, fewer than two percent of the 1,062 respondents reported they were ever faced with such a dilemma (9). One can try to explain this low percentage in several ways. The first and most obvious is to question the reliability of the survey or the sincerity of the respondents. The most commendable (but absurd) explanation would be that the respondents had developed their clinical skills so well that they were rarely challenged by clinical situations in psychiatry (10). Another explanation might be that the predictability with which emotional problems are subject to amelioration is not necessarily determined within the context of clinical skill (11, 12).

Still another possible explanation is that perceived skills of subspecialty psychiatrists so approximate the needs of patients who are referred to them that the psychiatrist respondents genuinely feel well prepared to undertake most of the activities asked of them. Such a situation was found in a study of patterns of referral of recently discharged psychiatric patients to vocational rehabilitation agencies (13). Hospitals referred primarily those patients who were considered "good risks" and amenable to vocational rehabilitation, and in turn the agencies saw and accepted primarily good-risk patients who were appropriate to their programs. It is possible, albeit improbable, that psychiatrists who are rarely challenged by an activity for which they feel ill prepared are seeing primarily those patients who are good risks and amenable to the psychiatrists' specific forms of treatment. And finally, whatever constitutes clinical skill in psychiatry might be of little relevance to the types of problems psychiatrists are asked to solve in numerous other areas of professional responsibility (8, p. 61). For example, a psychiatrist with a specific set of psychotherapeutic skills might conceivably find these of little or no value if he is the administrator of a community mental health center.

LACK OF EDUCATIONAL MODELS FOR SKILL DEVELOPMENT IN PSYCHIATRY

Medicine has institutionalized the belief that a clinical background is fundamental to any kind of medical activity, including research and administration. Psychiatry is no exception to this belief. But it is conceivable that skills in psychotherapy may not lend themselves to the skills needed (to stay with the example cited) for administering a community mental health center. If such is the case, can psychiatrists build into their educational models a timetable of anticipated skill development levels, or will the increasingly free choice in residency training programs allow the resident to cultivate that which he does best or values most at the expense of other skills, including clinical ones?

If, for example, a resident who has spent his first year in inpatient psychiatry and his second in outpatient psychiatry elects to spend a year in biochemical research, one cannot predict the extent to which his third-year experience might detract from his clinical skills. But it is conceivable that his peer-perceived level of clinical skills may be less than adequate as his skills in biochemical research increase. On which skill and by which peer group should he be reviewed? And if by more than one group, can the American Board of Psychiatry and Neurology (ABPN) anticipate how different psychiatrists with different sets of skills might influence the certification process? Or should the board examine for different skills at different points in the resident's education? And if so, what designated areas of psychiatric competence should be expected of the candidate, say at the end of his first year of residency, completion of residency, and after two years in his area of interest?

SKILL DEVELOPMENT AND CREDENTIALING IN OTHER SPECIALTIES

At least two other medical specialty boards have designated specific areas of competence, demonstrated through specialty board examination performance, as a minimal standard of certification in that specialty. A long-term analysis of skills contributing to successful achievement in board examinations in the field of orthopedics has been initiated to help determine which skills are to be attained by a specific time within the education (residency and postresidency) of the specialist (14). However, orthopedics is essentially "task oriented" and thus lends itself more readily than psychiatry to developing standards and guidelines specifying the subject content and skills necessary for successful completion of those tasks.

The American Board of Internal Medicine (ABIM) recognizes that "some candidates will have developed sufficient competence in the broad field of internal medicine that they can appropriately undertake the examination after devoting to general medicine the acceptable minimum period of two of the three required years of training . . ." (15). As of June 1972, the ABIM no longer uses its written qualifying exam (comparable to the written Part I of the ABPN exam) as a prerequisite to the oral certifying exam for candidates completing training after November 1971. Instead, the ABIM will require a more thorough description and evaluation of the candidate's graduate education performance by his residency program director. If the board finds the candidate's residency evaluation satisfactory, the candidate may then take the written exam, successful completion of which will certify him in general internal medicine. Presumably, a high correlation between success on the written qualifying exam and subsequent success on the oral certifying exam encouraged the ABIM to experiment with this change. The change has initiated at least two trends within graduate education in internal medicine that are relevant to the theme of this paper.

Successful completion of the written certifying examination encourages the candidate to apply for an increased choice of written and oral subspecialty examinations if he meets the training qualifications for the

subspecialty. In addition, the ABIM's greater reliance on residency program directors for evaluation of candidates will necessitate visiting programs at intervals to examine the efficacy of the internal review mechanism (16). One can hope that such visits will aid in developing better guidelines for subject content and skill development in the education of the internist. Whether graduate education programs in psychiatry can agree on what subject content and skill development a psychiatric resident should have mastered by a specific time in his education is currently unanswered. But such questions must be raised if psychiatry is to establish effective peer review standards.

If the low correlation between physicians' cognitive knowledge, as exhibited through test procedures, and task fulfillment, as observed in their clinical performance, is as great as suggested (17, 18), peer review standards in a specialty as poorly defined in performance levels as psychiatry risk severe ambiguity. It is highly improbable that psychiatry can convincingly justify its inclusion in any broad health insurance scheme unless it can more clearly define its function and performance levels. If these are defined, the task of maintaining the performance levels will fall largely to the organization responsible for "credentialing."

Psychiatrists' Interest in Board Review

In the survey (9) cited earlier, little surprise was evoked when 60 percent of psychiatrist respondents eligible to take ABPN examinations chose a board preparation course as a perceived educational need. Other high-interest areas were adolescent, forensic, and community psychiatry and psychosomatic medicine—again not unexpected findings. But the relatively low interest of the respondents in clinical examples of psychiatric syndromes, recent advances in clinical medicine, clinical assessment, organic therapies, and nosological problems was perplexing, since it was believed that these topics represented areas of clinical relevance to psychiatry.

Some reasons may be offered for this low response. It is possible that the topics did not appear clinically relevant to the respondents' practice needs. For example, if a respondent is primarily engaged in psychotherapy, his need for clinical examples of psychiatric syndromes, advances in clinical medicine, and nosological problems may be minimal. However, it seems reasonable that clinical assessment and organic therapies might be of some relevance to such a psychiatrist's clinical practice. On the other hand, it is possible that the respondents' interests were not necessarily correlated with topics that were more applicable to their clinical practice but rather ones that satisfied "credentials consciousness" (19).

CONTINUING EDUCATION AND "CREDENTIALING"

Of 391 psychiatrist respondents eligible to take ABPN examinations, 234 (60 percent) chose a board review course as a specific continuing education interest area. Of that number, a total of 127 have actually taken the course at the University of Southern California (USC) over the four years it has been offered. Only five of those who completed the course said they were not planning to take board examinations. When two others elected to repeat the course after they had delayed their examinations, it was with the goal of being better prepared for the day of reckoning. Only one board-certified psychiatrist who enrolled in and completed the course said he did so because he was interested in a good review of psychiatry and related fields. It is unlikely that these data reflect a consuming interest in clinically relevant material as much as they reflect a concern with being sufficiently prepared to withstand the credentialing process.

How well the course provided a vehicle for the achievement of that goal is not adequately known, since the ABPN does not release statistical data about candidate performance. Nor does the board release "condition" or "fail" statistics in *The American Journal of Psychiatry* issues listing candidates who passed. But the respondents' opinions of how well the course contributed to their goals indicated that they perceived it as the main and most significant source of board preparation as well as an effective educational experience. It is equivocal whether the course provides an incentive to participate in future USC continuing education programs, since 35 percent of the enrollees had participated in previous USC continuing education programs, but 43 percent of enrollees in the intensive review course who had not previously attended USC continuing education programs did so after completing the intensive review course.

More crucial to the theme of this paper, however, is whether intensive review provides an educational experience that broadens the psychiatrist's knowledge of his field and enhances his clinical skills. Data gathered from testing participants on the material taught as well as the simulated oral examination at the end of the review indicated that the psychiatrist's cognitive knowledge of the field was very likely enhanced. But it is highly equivocal whether clinical skills, if definable and then measurable, are significantly altered by this learner-influenced board review course.

For example, pre- and postcourse simulated oral examination scores demonstrated no average increase in clinical skills; those entering the course with an above-average score in clinical psychiatry actually *decreased* their clinical psychiatry scores after the course. Those scoring below the mean before the course increased their scores after the course. Explanations for this have been reported elsewhere (20). More significantly, the results call into question the extent to which a candidate may, intentionally or not, overemphasize the didactic aspects of his specialty at the expense of an area in which he has already demonstrated above-average competence and on which the oral examination should concentrate, namely, interviewing skills.

Even more perplexing is the observation that those initial above-mean scorers who lowered their clinical psychiatry scores at the end of the course had increased their scores in basic neurology, basic psychiatry, and clinical neurology. This calls into question the relationship between clinical and basic psychiatry and also raises the

practical problems of what one tests for in credentialing the clinically competent psychiatrist. Presumably such a psychiatrist should be able to utilize flexible interviewing skills with an extensive but finite variety of patients and support a diagnosis and treatment plan based on his observations as well as his experience and knowledge of the literature. Such a clinician would certainly be considered competent, but the extent to which basic knowledge of psychiatry and neurology correlate with that competence (or more importantly, patient care) is still to be determined. For example, 83 percent of the psychiatrists in the intensive review course felt the neurology portion of the review was relevant to material needed for board examination, but 65 percent felt such material would not benefit their patients.

Thus, at a time when we are being asked to identify continuing education needs and interests, it appears that a very motivated majority of board-eligible psychiatrists define their needs in terms of what may credential them rather than what may possibly enhance clinical skills, therapeutic relevance, and patient care. This observation forces one to ask how incentives for quality control and effective peer review can be implemented within a continuing education area of high interest such as board review.

EDUCATION, PROFESSIONAL ROLE, AND COMPETENCE

If one concedes that the traditional peer review process is probably more vulnerable to "cronyism" and professional patronization than is the elitist cadre of board examiners who test for professional competence, it is likely that the board examination process can serve as a more effective peer review instrument. But review for what? Certainly completion of a basic science review in preparation for a multiple-choice test would hardly be a demonstration of the psychiatrist's ability to deliver effective mental health care. An adequate review of the current literature might provide the candidate with the comfort and illusion that he knows his field and therefore demonstrates professional competence. It is even questionable whether a professionally incompetent psychiatrist who knows basic science and literature is potentially less harmful to the patient than the incompetent one whose shortcomings are more demonstrable. Specifically, such shortcomings might be more evident in the area of patient management.

To the psychotherapist whose practice consists of long-term, insight-oriented therapy with outpatients, the concept of patient management might be viewed as pejorative or at best manipulative. The particular practice needs of such a psychiatrist might not lend themselves readily to continuing education through greater exposure to patient-management problems. Rather, continuing education programs and peer review methods that would be most effective for him might involve comparative psychotherapy experiences in conference or videotape form, with specific questions derived from such learning formats.

The tailoring of educational programs to the perceived needs of psychiatrists redirects our attention to the issue of what a psychiatrist does. This is not easily answered. I have already suggested what a clinically competent psychiatrist should be able to demonstrate in a credentialing examination. But what about the psychiatrist who has demonstrated such clinical competence, is credentialed accordingly, and has moved into, say, community mental health or inpatient psychiatry? Presumably his interest (combined with many other factors) guides his specialty choice. However, is that interest, along with the other factors, sufficient to motivate his continuing self-assessment of the knowledge and skills needed for competence in that area? Does his being a credentialed, clinically competent psychiatrist qualify him to direct a community mental health center or an inpatient service? If not, what skills should we expect of such a psychiatrist in order for him to fulfill these tasks? Could the work of the Committee on Certification in Administrative Psychiatry be expanded to allow for the clearer definition of such skills? More importantly, what obligation does organized psychiatry have to the patients seen in a mental health center or inpatient service vis-à-vis establishing criteria for competence in these still unofficial subspecialties? In the absence of adequately demonstrated continuing education relevant to patient care in a particular subspecialty, organized psychiatry might opt for more effective standards of peer review even to the point of recredentialing the board-certified psychiatrist in his subspecialty.

PATIENT-MANAGEMENT PROBLEMS IN CONTINUING EDUCATION AND PEER REVIEW

For those psychiatrists who will be practicing increasingly in the public sector and thus must be responsive to health legislation guidelines and to association with other health professionals, and who must be equipped for short-term, directive forms of mental health services, the patient-management approach toward continuing education seems appropriate. Such efforts can be constructed so as to include not just simulations relevant to patient care but also an assessment of the respondent's knowledge of legislation, program development, and community organization. The emphasis of each subspecialty group can be built around a variety of examples of patient-management problems; but the questions as well as the knowledge and skills brought to the problems would vary with the subspecialty examination.

Four related phenomena in psychiatry support greater emphasis on patient-management approaches in continuing education and peer review. The first involves the American Board of Psychiatry and Neurology itself. In 1966 the ABPN converted its format from a combined written/oral examination to a screening written examination devoted largely to basic sciences and a final oral examination in basic and clinical psychiatry and neurology (21). In 1970 the format changed again: basic neurology was made part of the written examination and was excluded from the clinical neurology portion of the oral

exam except as it related to clinical problems. Although the change occurred for many reasons, its effect may enhance the patient-management aspect of the oral board examination process because more time is provided to evaluate candidates' performance in the patient interview, and the anxiety concerning the oral basic neurology examination felt by psychiatrists not accustomed to using such information may be reduced. If the latter occurs, more psychic energy would be available for effective clinical performance. Second, the APA Office of Continuing Education has reduced the number of administrative psychiatry problems and has increased the number of patient-management problems in its self-assessment test (22). Third, the hospital record-keeping system developed by Weed (23) incorporates a patient-management approach to problem-oriented records. Studies of the Weed system suggest that, in addition to more effective record keeping, it provides a potential format for effective peer review and continuing education in medicine generally (24, 25). The application of the Weed system to psychiatric record keeping is also eliciting some favorable expectations (26, 27). But the obstacles may be even more formidable than for the rest of medicine because of the numerous and complex functions that psychiatry carries out. Patient-management problems, as part of the written and oral portions of the ABPN examination, may force a better definition of these functions and a reevaluation of psychiatry's role in the extension of health care in this country.

CONCLUSIONS

Voluntary continuing education programs have been endorsed by organized medicine; self-assessment tests have been offered in the hope of developing an effective alternative to mandatory continuing education. Medical skills—and specifically, psychiatric skills—will be under closer scrutiny and in need of more specific identification. When asked to define their continuing education interests, an impressive number of psychiatrists indicated board review as a primary one. I suggest that board review courses and the ABPN examination itself be considered as a more effective vehicle for continuing education and peer review. I consider the patient-management approach to identifying professional competence among psychiatrists a superior means of implementing the kind of continuing education that is relevant to effective peer review and the delivery of mental health services.

One can hope that the ABPN will experiment with greater emphasis on such problems and share the results of their evaluation in an effort to establish more effective guidelines to assess competence in carrying out the numerous functions of the psychiatrist. In the absence of extensive continuing education in psychiatry and the cooperation of the ABPN in assessing the relevance of certification as it relates to effective patient care, organized psychiatry may be forced to consider periodic mandatory recertification in an effort to assure adequacy of peer review.

Psychiatry Residents as College Teachers: An Evaluation of a Training for Teaching Program

BY ALAN M. LAZERSON, M.D.

Questionnaire evaluation of a recently developed training experience within an overall program designed to prepare psychiatry residents to become better teachers revealed that the project was popular with students, resident teachers, and the college administration. Of the 60 students polled, over 80 percent rated their instructor and their course as above average or better. Eighty-five percent of the responding students felt that they had learned a great deal, and the residents reported that it was also an excellent learning experience for them.

OVER THE PAST SIX YEARS the Division of Psychiatry of Boston University School of Medicine, in conjunction with the Boston University School of Education, has developed a Training for Teaching Program designed to prepare residents in psychiatry to become better teachers. This program was initiated not only to meet a long-felt need, but also as a result of an increasing demand for psychiatrists to teach in professional, university, and community settings, a demand propelled by the force of the community mental health movement. The program is rare in professional education in that mastery of content alone is not considered to be sufficient background for teaching. Rather, it is felt that teaching experience under supervision, along with a systematic consideration of the principles of teaching and learning, is vital in the development of the psychiatrist as a teacher.

This report describes a recently developed training experience within the overall program and highlights the results of one semester. As part of a graduated series of teaching opportunities available each year, it offers an unusual chance for a supervised teaching experience with a variety of students at Metropolitan College, the evening division of Boston University.

It should be stressed that this experience in the Training for Teaching Program is the middle step in a program that spans the three years of training. It builds on a brief, intensive first-year experience in teaching about adolescence to undergraduate education majors. The third year offers additional diversity and may include additional supervised teaching at Metropolitan College, the School of Medicine, or a community mental health facility. Other activities include regular conferences on typical teaching issues or problems. From the beginning, all residents have the advantage of being able to speak from their own teaching experience, and this increases their active participation.

Dr. Lazerson is Associate Professor of Psychiatry and Director, Training for Teaching Project, Division of Psychiatry, Boston University School of Medicine, 80 East Concord St., Boston, Mass. 02118.

This work was supported by Public Health Service grant MH-10509 from the National Institute of Mental Health.

The author wishes to express his appreciation to Drs. William Gurnack, Stephen Howard, Peter Musliner, and Robert Ziegler not only for their assistance in compiling the data but also for their dedication to the teaching experience that this evaluation reflects.

THE METROPOLITAN COLLEGE TRAINING EXPERIENCE

Setting

The courses are developed and taught by the residents in Metropolitan College classrooms as full-credit courses that are elected by regularly enrolled students. Classes meet weekly in the evening and therefore do not interfere with the residents' other training responsibilities.

To provide an administrative structure for the program that in itself would contribute to training in teaching, an academic department of Mental Health Studies was established by an arrangement between the college and the Division of Psychiatry. The residents make up the faculty of the department, and I am its coordinator.

Students

The students at Metropolitan College represent a heterogeneous population. Many are enrolled in other colleges. Some are considerably older than the average student, and some already hold degrees. Eighty-two percent of the 60 students in this study were in full- or part-time employment. The residents thus have a unique opportunity to teach a diverse group that more closely approximates the mental health groups that they may eventually be teaching than a typical undergraduate or medical student population.

During our two-year experience at Metropolitan College, nine residents have offered 18 full-semester courses to approximately 350 students.

Course Content

The subject matter of the course is chosen by the resident following consultation with the psychiatry faculty and the Metropolitan College administration. Typical content offered by the resident may be an area of research or clinical interest (e.g., drug use and abuse), theoretical interest (e.g., child development), or an elaboration of his adolescence course.

Total	91	60	31	22	6	1

Teaching Under Supervision

Early in the project we observed that activity in learning was a necessity; talking about teaching was not the same as doing it. Residents and faculty decided that resident-teaching under supervision offered the best way to achieve the aims of the program.

The resident is therefore observed with varying frequency in his teaching by the faculty of the School of Education, faculty psychiatrists, and his peer teachers. After his class he is provided with feedback about his teaching style and is questioned about his goals and his methods of evaluation of student learning.

METHODS OF EVALUATION

Outline

The overall evaluation of this teaching experience included data of various types from a variety of sources: 1) evaluation of the resident instructors by the Metropolitan College students (from a questionnaire), 2) evaluation of the courses by the Metropolitan College students (from two questionnaires), 3) evaluation of their own learning in the course by the Metropolitan College students (questionnaire), 4) evaluation of their own learning-to-teach experience by the residents (through informal discussion and a subjective questionnaire), 5) evaluation of the overall results by the Metropolitan College administration, 6) impressions of the psychiatry faculty in the program (from observation and discussion), and 7) impressions of the faculty from the School of Education (from observation and discussion).

We recognize that this evaluation lacks not only control subjects, such as residents who did not participate in the program, but also longitudinal before-and-after comparisons of each resident as he moved through each phase of the program.

Description

At the end of the first semester of the 1971–1972 year the college evaluated, through an anonymous student questionnaire, 85 percent of its total course offerings. Four of our five courses and three of the four instructors were included, by random selection, in this evaluation.

Of 62 items used, several seemed especially pertinent to this evaluation. One of the questions provided an overall evaluation of the instructor: "In comparison with all the instructors I have had, both in high school and in college, this instructor was: a) one of the best, b) above average, c) below average, d) far below average."

Favorable responses to this question (i.e., a *and* b) were added, and a "favorable" percentage of the total number of students responding to the questionnaire was computed for each department. An all-college favorable percentage was obtained. In addition, the departments were put in a rank order on the basis of this percentage.

An overall measure of the Metropolitan College students' evaluation of the course was taken from responses to another question on this questionnaire: "In comparison with all the courses I have had, both in high school and in college, this course was: a) one of the best, b) above average, c) below average, d) far below average."

A second questionnaire, which I devised primarily to determine the background and interests of the Metropolitan College students, included a question that attempted to assess the "general feeling about this course: a) pleased, b) satisfied, c) dissatisfied, d) not up to high expectations."

The residents were to distribute these to their students at the end of the course.[1] In those cases where this was not possible, the questionnaire was mailed to the students, with an expected paucity of returns. Fortunately, however, the resident whose course was not covered in the Metropolitan College questionnaire (resident D) was able to poll his students directly.

An overall assessment of the Metropolitan College students' learning was taken from a third question on the Metropolitan questionnaire: "In this course, I learned a great deal: a) definitely yes, b) yes, c) definitely no, d) no."

The residents' evaluation of their own learning-to-teach experience was obtained by both informal discussion and a six-item questionnaire that included the following questions:

1. What were your expectations about this experience?
2. In what ways did the experience fulfill or differ from your expectations?

[1] Unfortunately, for a variety of reasons not all students could be polled in person.

TABLE 2
Students' Evaluation of Courses

Course Instructor	Students	Responses	One of the Best	Above Average	Below Average	Far Below Average
Resident A	31	21	11	8	1	1
Resident B	15	10	0	7	1	2
Resident C (course 1)	25	12	9	3	0	0
Resident C (course 2)	20	14	7	5	1	1
Total	91	57	27	23	3	4

3. Give your evaluation of the response and progress of your students.
4. What suggestions have you about changes which would have made your experience more valuable?

The final three methods of evaluation are based on overall impressions and are self-explanatory.

RESULTS

The responses to the questions used to measure the students' evaluation of the instructors, courses, their feeling about the courses, and their own learning are presented in tables 1–4, respectively.

A total of 28.3 percent of all the Metropolitan students answered, "one of the best" to the question rating the instructor, and 49.8 percent responded, "above average." The total of these two responses, grouped as favorable, was therefore 78.1 percent for all the courses in the survey.

The comparable data for instructors in the Department of Mental Health Studies was 49.2 percent for "one of the best" and 34.9 percent for "above average," totaling 84.1 percent as favorable. In the rank order based on the favorable percentage, the department ranked ninth of the 22 departments included in the study.[2]

To complete the Metropolitan data, 14.7 percent of all the students rated all the instructors as "below average," 2.4 percent rated them as "far below average," and 4.6 percent did not answer. For the courses in our department the comparable responses were 9.5 percent, 1.6 percent, and 4.8 percent.

The method used for the residents' evaluation of their learning-to-teach experience makes it difficult to tabulate the responses that they gave. Several quotations, however, may illustrate:

Resident A:

> My experience in my several years of teaching at Metropolitan College under the aegis of the Training for Teaching Program has been quite positive. The actuality of teaching classes has necessitated deepening my thinking as a practitioner, both of psychiatry and of teaching, and has forced me to grapple with the very real problems and satisfactions of teaching. Instructing in the same subject for several semesters has further given me the opportunity for experimentation in didactic techniques and classroom dynamics.

Resident B:

> I expected it would be a good experience, which indeed it was. I had favorable feelings from the first [year] experience, and it was repeated this year. . . . The students were most helpful in helping me define my role as teacher, and the result was a very favorable interaction between myself and the students.

Resident C:

> I expected a group of people who were interested in learning how people worked, either for personal or intellectual reasons, and who felt that their own experiences and their experience of the literature would be mobilized to create that understanding.
>
> I was continually amazed at their capacity to reflect and make use of very varied resources to determine what was going on.

Resident D:

> My expectations were largely met through my experience teaching. . . . I found the experience valuable in that I observed, on their and my own part, both ends of the spectrum of rapport. I can't suggest any changes. I feel that what I need is merely more experience and the chance to test out my hypotheses concerning the past term by going at it again next term.

The following quotation is an excerpt from the evaluation of the overall results by the Metropolitan College administration (1).

> Now that we are approaching the end of the first year of offering the courses, we have made the following evaluation:
> 1. The quality of the teaching and the content of the courses are excellent and have lived up to our expectations in every way.
> 2. The program was very helpful toward our continuing efforts to enrich our curriculum with courses of quality and relevance to students' contemporary interests and needs. . . .
> 5. We were able to demonstrate our interest in fulfilling our

[2] These percentages are slightly different from those which would be derived from table 1, since three of the students who responded to the questionnaire did not check any answer to this question. These students are included in the Metropolitan data but not in table 1.

TABLE 3
Students' Feeling About Courses

Course Instructor	Responses	Pleased	Satisfied	Dissatisfied	Not up to High Expectations
Resident A	23	14	8	1	3
Resident B	3*	3	0	0	0
Resident C (course 1)	6*	6	0	0	0
Resident C (course 2)	2*	1	0	1	1
Resident D	17	8	8	1	6
Total	51	32	16	3	10

*By mail.

commitment to the community by offering courses of interest to professionals from various agencies in the Greater Boston area.

Needless to say, we are very supportive of the program and hope it will continue.

Along with Dr. James Skinner, former director of the program, I have had the opportunity to see each of the residents during his teaching experience. Among many aspects observed, the enthusiasm of each teacher, his interest in his students and his eagerness to have them learn, and a versatility in approach coupled with a wide variety of subject matter were always apparent. On each visit there appeared to be a learning alliance (2) between the teacher and most of his students.

The following quotation is an excerpt from the impressions of the supervisors from the School of Education (3).

> The residents' . . . classes at Metropolitan College exhibit as a group many of the sensitivities, approaches, and techniques associated with good teaching. They reveal sensitivity to the centrality of the student in the learning enterprise by involvement of students in class planning, by interspersing lecture with discussion, and by seeking and utilizing student feedback as their courses progress. . . .
>
> All in all, the residents seem to be utilizing insights acquired during their earlier experience with undergraduate students. They also reflect their psychiatric training in their interactions with students and by their sensitivity to the learning environment.

DISCUSSION

Several results of this experience may be readily identified.

Clearly apparent is the popularity of the program on the part of the residents, the students, the administration, and the program faculty. It is striking that of 60 responses from the students (table 1), over half considered their resident to be one of the best instructors they had had in high school or college, and 53 (88 percent) considered him at least above average.

While the residents as a group were rated only six percentage points above the favorable mean for the college, they were 21 percentage points above the mean for the "one of the best" rating. These data help to meet the problem introduced by the necessity for a forced choice on this questionnaire, and the validity of the results is enhanced by the multiple sources of data.

While the results of the second questionnaire (table 3) are far from complete, they at least do not contradict the data on the first questionnaire. Since the duplicated data on resident A's course is similar—22 of 23 students were "pleased" or "satisfied" with the course on questionnaire 2, as compared with 19 of 21 who rated the course as "one of the best" or "above average" on questionnaire 1 (table 2)—we may make the assumption that the data would be comparable for the others. Thus the main value of this questionnaire for an evaluation of the results is that it completes the data by including the course of the missing resident D. With 16 of 17 students (94 percent) "pleased" or "satisfied" with his course, this follows the pattern of the overall total of 88 percent responding, "one of the best" or "above average."

Students and teachers were both learning. Not only did 53 of 62 of the responding students (85 percent) feel that they had learned a great deal (table 4), but the residents reported that it was also an excellent learning experience for them.

Although it is not indicated in the data supplied, the residents also learned a great deal about their subject. Facing a situation that requires one to teach what he knows is a major stimulus to learning, and the residents found themselves independently thinking, reading, and

TABLE 4
Students' Evaluation of Whether They Learned a Great Deal

Course Instructor	Responses	Definitely Yes	Yes	Definitely No	No
Resident A	24	11	10	0	3
Resident B	11	1	7	2	1
Resident C (course 1)	13	3	10	0	0
Resident C (course 2)	14	5	6	0	3
Total	62	20	33	2	7

learning more and more about what they had chosen to teach.

Perhaps these results should not be surprising. Young psychiatrists, interested in their subject matter, trying their wings in their first major teaching venture, with support and available supervision and consultation, bring a freshness to their teaching that is contagious.

We believe that these findings would be approached in a training experience for a young professional in any discipline provided with a similar program. However, it is noteworthy that, when the project first began in 1966, a poll of similar residents indicated that had they not become physicians their occupational choice would have been teaching.

A School for Medicine Men

BY ROBERT L. BERGMAN, M.D.

The author discusses the establishment and training program of a Navajo school for medicine men and his involvement in it. From a psychiatrist's point of view, he describes the nature of the curative ceremonies and a few of what he perceives as their effects. He also discusses his role in teaching the medicine men and trainees something about medicine and psychiatry and their reactions to these.

THIS PAPER IS AN ACCOUNT of how a Navajo community set up its own medical school and how a non-Indian psychiatrist became involved in it. In order to understand what happened one must have some acquaintance with the nature of Navajo medicine. This subject has received an enormous amount of attention from anthropologists and other behavioral scientists. I will make no attempt here to review the extensive anthropologic literature except to recommend the great works of Haile (1), Reichard (2), and Kluckhohn and associates (3–6). The psychiatric literature is less extensive. It includes the early article of Pfister (7), which seems to me to be remarkably insightful and sound in spite of having been based on very little and quite second-hand evidence. The Leightons (8) in 1941 described Navajo ceremonials beautifully and explained many of their beneficial elements. Sandner (9) reported his work with Navajo medicine men to the APA three years ago. Almost everyone agrees that the ceremonies work.

BACKGROUND

Navajo practitioners generally fall into three categories. The herbalists know a variety of medicinal plants, which are used primarily for symptomatic relief. The diagnosticians are shamans who work by inspiration. By one of several techniques, such as hand trembling, crystal gazing, or star gazing, they divine the nature and cause of an illness and make an appropriate referral to a member of the third and highest status group, the singers. The singers (I will use the terms "ceremonialist," "medicine man," and "singer" synonomously) do the only truly curative work, and it is a school to train them that I will be discussing.

Navajo nosology classes diseases by etiology; identical illnesses often have similar symptoms, but they need not. Note that psychiatric nosology is similar, e.g., depression is often characterized by insomnia, but sometimes the reverse can be true. A seriously oversimplified statement of Navajo etiology is that disease is caused by a disharmony with the universe, including the universe of other men. A singer restores this harmony by performing a ceremony proper to the case. Little or no reliance is placed on herbs or other medicines and, as is the case with psychiatry (at least from the psychoanalytic viewpoint), this absence of organic measures confers high status.

No one seems to know precisely how many ceremonies there are, but there are many. Important ones last five or nine nights and are difficult and elaborate to a degree approached among us physicians, I think, only by open heart surgery. The proper performance of a major sing requires the presence of the entire extended family and many other connections of the patient. The immediate family must feed all of these people for days. Many of the people present have important roles in the performance, such as chanting, public speaking, dancing in costume, leading group discussions, and many other prescribed activities of a more or less ritualized nature. For the singer himself the performance requires the letter-perfect performance of 50 to 100 hours of ritual chant (something approaching the recitation of the New Testament from memory), the production of several beautiful and ornate sand paintings, the recitation of the myth connected with the ceremony, and the management of a very large and difficult group process.

Non-Navajo explanations of why all this effort helps anyone tend to be rather offensive to the medicine men themselves, and *their* explanations, if they should feel like giving any, tend to be unsatisfying to us since they are based on the supernatural. The difference may not be as great as it appears, however. Traditional Navajos talk frequently in symbols: "We are glad you came from Washington to talk with us. There are many mountains between here and Washington," which translates as, "Communication with the federal government is difficult. We are glad you are making an effort to improve it." They also reject the notion that they are using figures of speech. They do not attach as much significance to the distinctions among different levels of reality as we do, and like some poets, they reject as stupid and destructive any attempt to translate their words into ordinary language. Though it seems to me that their myths and chants

are symbols of human social-psychological forces and events, they would regard such a statement as silly and missing the point. Nevertheless, I will make a slight attempt in that direction.

THE RITUALS

For the past six years, I have been practicing psychiatry among the Navajo people. I have often referred patients to medicine men (who in turn occasionally refer patients to me). I have also often consulted medicine men, and patients have often told me about the medicine men's traditional cures and their feelings about these cures. It seems to me, although my knowledge of the sings is very limited, that the ceremony performed is almost always symbolically appropriate to the case. Pathologically prolonged grief reactions, for example, are almost always treated with a ceremony that removes the influence of the dead from the living and turns the patient's attention back toward life. "Treatment of a dream by a dream," Pfister called it.

It seems to me that the singers and we psychiatrists are the converse of one another with regard to our attitude toward ritual. To them ritual is the main focus: What is unvaryingly their practice from one case to another is at the center of their thought. Informal interaction with the patient and his family is considered important in an informal sort of way. This kind of interaction is not what is taught explicitly but only what is taught by the by. Our ritual, which I would argue is fairly elaborate, is not taught as the central part of psychiatry; rather, the more varying interaction is taught explicitly to psychiatry residents—ritual being taught by the by. In any event the singers do manage an intricate family interaction that, I think, has several important effects: 1) the patient is assured that his family cares for him by the tremendous effort being made; 2) the prolonged and intense contact makes it inevitable that conflicts are revealed and, if things are handled skillfully, resolved; and 3) a time of moratorium and turning point are established.

At the time I first heard of the medicine-man school in 1967, I was already quite convinced of the value of Navajo medicine. Aside from the cases I had seen, I was greatly influenced by my contact with a singer named Thomas Largewhiskers. Mr. Largewhiskers, who is now 100 years old, agreed to be my consultant and to teach me a little of what he knew. I first looked him up after seeing a formerly psychotic patient who attributed her remarkable and well-documented improvement to him. At the time of our first meeting I tried to explain what I do and said that I wanted to learn from him. He replied, "I don't know what you learned from books, but the most important thing I learned from my grandfathers was that there is a part of the mind that we don't really know about and that it is that part that is most important in whether we become sick or remain well." When he told me some of his life story it impressed me that he had become interested in being a singer when, as a young man, he had had an accident and the singer who took care of him explained that it had been unconsciously determined.

Mr. Largewhiskers and many other extremely old men are still practicing very actively. There is a growing demand for their services—growing because the population is increasing and their belief in traditional medicine is continuing. The trouble is that younger people are not becoming singers. The reasons behind the lack of students are largely economic. To learn to perform even one short ceremony takes at least a year of full-time effort. To learn a major ceremony takes much longer, and many medicine men know several. Since the end of the old herding economy, almost no one can afford to give up earning a living for such a long time. At the time of starting the school for medicine men Yazzie Begay, one of its founders, said, "I have been acquainted with several medicine men who have recently died. They were not able to teach the ceremonies which they knew to their grandchildren or to anyone else. Today their sacred instruments and paraphernalia are sitting unused."

THE SCHOOL

The school is at Rough Rock, Ariz., a community near the center of the Navajo Reservation. It is part of the Rough Rock Demonstration School, the first community-controlled Indian school. The Demonstration School was started in 1965, when the Bureau of Indian Affairs (BIA) gave the buildings and equipment to a nonprofit corporation of Navajo leaders called Dine, Inc. Dine helped the Rough Rock chapter of the tribe set up and elect its own board of education (no one on the original board could speak English and all were ceremonialists) and then contracted with the board to operate an elementary boarding school. BIA contributed funds that would have been equal to the budget of such a school if they had been operating it; funds also came from the Office of Economic Opportunity (OEO) and other sources. Soon after the school began operations in 1966, the people became convinced that their ideas really were taken seriously in its daily workings, and several local people suggested setting up the medicine-man school to the board. It was pointed out at a board meeting that white people have medical schools and give students scholarships to attend them and that what was needed most on the reservation were new medicine men. Therefore they felt Rough Rock should set up a school for singers and provide scholarships.

The idea was taken up enthusiastically by the board, and the details were worked out over the course of the next year. It was decided to alter the traditional method of teaching and learning sings as little as possible. (The old way is by apprenticeship and takes place in the teacher's home.) It was also decided that each medicine man would teach two apprentices of his own selection; that is, application for admission to the school would be made by trios consisting of a medicine man and two trainees. The school board would select among them on the basis of the medicine man's reputation, the trainees'

apparent ability, and the importance of and threat of extinction to the ceremony that was proposed to be taught. The medicine men were to be paid a very modest salary and the trainees considerably less for their subsistence.

OBTAINING FUNDS

Ever since the Demonstration School started, I had been going there once a month or more to consult with the guidance counselor and teachers. At one time the school administration, at the direction of the board, was preparing a project proposal in an attempt to obtain funds; I was asked to attend a meeting about the project, and here my support for the proposal was enlisted. This was the first of several project discussions in which I took part, and ultimately the board kindly included me in the proposal. It was decided that I should meet regularly with the trainees to discuss non-Navajo medicine, particularly psychiatry. I strongly suspect that my inclusion was a move to make the project look more reasonable to funding agencies.

I flatter myself that from time to time my colleagues in the school and the trainees have been glad to have me around, but I am sure that I have gained much more from this than they have. Before the project could materialize, however, we had to obtain funds.

The first proposal was made to OEO, which turned it down. The second proposal went to the Training and Special Projects Branch of the National Institute of Mental Health (NIMH). This one was accepted, although not, I suspect, without some trepidation. At the time of the site visit by NIMH it became apparent how many mountains there really were between Rough Rock and Bethesda, Md. First of all, the weather became very bad and the site visitors felt they were stranded in Albuquerque, which is 250 miles away from Rough Rock. Luckily the school board was able to go to Albuquerque, so we had a meeting. Two incidents seemed to me to epitomize the meeting. The first was a question from the visitors: "How can a project that supports the continuance of superstition promote mental health?" The reaction of the ceremonialist school board members was more restrained than I had expected. They answered at length, and I added my endorsement. The visitors seemed satisfied. Later one of them, in leafing through the documents, said, "The project director is to be full-time, and the salary listed here is $5000. Can that possibly be right?" When that question had been translated, Mr. John Dick, the director in question, who was a medicine man and a former school board member, asked anxiously, "Is it too much?" I am very grateful that the project was funded, and I know that the board is also appreciative.

THE TRAINING PROGRAM

The work began in September 1969 and is still continuing. There are six medicine men and 12 trainees. Most of the original trainees are still in the program. One of the faculty members died during the first year and was replaced. The ceremonies being taught so far have been one and two nights in length, and almost all of the trainees have completed learning them. Soon they will be performing them for the first time. They will then go on to major ceremonies. Although the lessons (excluding the ones I teach) are conducted at various homes scattered over considerable territory in which there are no paved roads, Mr. Dick as director maintains close supervision. He travels to each home and watches over the teaching and its results. As the trainees have progressed, he and other medicine men have tested them. My only criticism has been that Mr. Dick's supervision seems rather harsh at times. He has demanded continuous effort and has been very hard on some people whom he surprised when he thought they should be working and they weren't. Still, apart from minor professional jealousy, the group's morale seems high. The program has been well accepted, and there clearly will be a demand for the services of the graduates. Other communities are trying to start similar schools. Recently one of the medicine men had one of his students perform a sing over him.

My sessions are a full day every two weeks. Before I started holding them I met with the medicine men to describe what I intended to do and to ask their permission. To my great pleasure they not only agreed to my plans but said they would like to attend along with the trainees. Attendance has varied from time to time, but usually most of the trainees are present as well as three to five of the medicine men. During the first year I talked about somatic medicine, attempting to cover elements of anatomy, physiology, pathology, diagnosis, and treatment. I discovered that the entire group, including the trainees, had considerable knowledge of anatomy and some of physiology. The sessions were lively. The medicine men and the trainees enjoyed trying out stethoscopes, otoscopes, opthalmoscopes, and blood-pressure cuffs. Microscope slides of blood smears and pathology specimens were also very popular. In return I was learning more about ceremonial practice, although not as much as I was to learn the next year when we began discussing psychology.

One of the high points of the first year was a visit that the group made to the Gallup Indian Medical Center. It was characteristic, I thought, that the two things the medicine men most enjoyed seeing at the hospital were an operation and a particularly good view of a sacred mountain peak from the windows of the psychiatric ward. They also had criticisms and suggestions. They were horrified by the pediatric ward because the children were so lonely. They kept asking, "Where are the parents?" They urged that better provisions be made for parents to stay with their children. They also suggested that we build two hogans at the hospital for ceremonial purposes. They remarked that they all had performed brief ceremonies in the hospital but that they could do more in a real hogan. They said that the medical staff could see the patients during the sing and could go back and forth if necessary. Their suggestion still has not been followed, but I hope that it will be soon.

During the second year I began discussing psychiatry, and in this area there has been more of a two-sided interchange. We have spent much time on European and Navajo notions of the unconscious, a subject in which difficulties in translation have been great. Navajo metapsychology still largely eludes me, but it is clear that the medicine men know about the dynamic interpretation of errors and dreams. We spent a great deal of time discussing dreams and were pleased to discover that all of us followed the same custom with regard to them. We all, it turned out, spend our first waking moments in the morning contemplating and interpreting our dreams. One of the medicine men gave an example. He had dreamt about an automobile accident and said that that kind of a dream meant something serious was going on within him and that in order to prevent some disaster from happening to him, it was important to perform a chant about it.

There has been a good deal of case presentation on both sides, particularly, for some reason not clear to me, regarding returned Viet Nam veterans. My feeling of trust and closeness to this group ultimately became such that I presented my own case, describing some things that had led me to enter my analysis and something of the analysis itself. When I finished this rather long account, one of the singers asked me the name of my analyst and where he is now. When I told him, he said, "You were very lucky to find a man who could do so much for you. He must be a very intelligent person."

Another high point for me was demonstrating hypnosis. The group ordinarily looks half asleep—as seems to be the custom with medicine men in meetings. This was unnerving at first, until I found out from their questions and comments that they had been paying very close attention. When hypnosis was demonstrated, however, they were obviously wide awake, although at times I wondered if they were breathing. Working with a carefully prepared subject (I was unwilling to face failure before this audience), I demonstrated a number of depth tests, somnambulism, age regression, positive and negative hallucinations, and some posthypnotic suggestions. When I was done, one of the faculty members said, "I'm 82 years old, and I've seen white people all my life, but this is the first time that one of them has ever surprised me. I'm not surprised to see something like this happen because we do things like this, but I am surprised that a white man should know anything so worthwhile." They also pointed out the resemblance of hypnosis to hand trembling, a diagnostic procedure in which the shaman goes into a trance and his hand moves automatically and indicates the answers to important questions. After we had discussed the similarity, they asked that my subject, a young Navajo woman, diagnose something. I objected, saying that neither she nor I knew how to do this and that it was too serious a matter to play with. They insisted that we try, however, and finally we decided that a weather prediction was not too dangerous to attempt. They were particularly interested in the weather at that time because we were in the midst of an especially severe drought, and someone in the community had predicted that it would continue for another year. When my subject was in a deep trance, I instructed her to visualize the weather for the next six months. She predicted light rain within the week, followed by a dry spell of several months and finally by a good rainy season in late summer. I make no claim other than the truthful reporting of facts: She was precisely correct.

My involvement in this project has, of course, been extremely interesting to me. It is hard, however, to assess the effects of the project on the medicine men and on me. The medicine men say that they know better when and how to refer patients to the white doctors, and I think they feel more kindly toward us. In turn, I feel better able to understand my Navajo patients and know better when to refer them to medicine men. I have adopted some Navajo styles of thought, I think. I use hypnosis more than I used to. And one of my Navajo colleagues in the Indian Health Service Mental Health Program claims that I try to act like a medicine man all the time.

Psychiatry in South Korea

BY SUK C. CHANG, M.D., AND KWANG-IEL KIM, M.D.

A study of the developmental history of psychiatry in Korea is instructive since in Korea the forces of tradition (particularly shamanism, folk medicine, and religion) and the forces of modernization are sensitively reflected.

MODERN PSYCHIATRY has a rather short history in Korea. Introduced during the Japanese occupation, which lasted from 1910 to 1945, it was descriptive-organic (Kraepelinian), the model prevailing in Japan at that time (1). Only a few psychiatrists were trained at Keijo Imperial University (now Seoul National University); consequently, when Korea regained her independence in 1945 at the end of World War II, psychiatry in Korea had a very narrow base.

In traditional Korean society the need for psychiatry seemed less urgent than the need for other medical specialties that have more visible and more clearly defined ailments to deal with. Also, Korean society had a repertoire of built-in sociocultural mechanisms that had a preventive or even curative effect on man's psychological distress. Four such traditions can be briefly described.

Shamanism, the earliest religion in Korea, was introduced there during prehistoric times from northeast Asia. It is still prevalent in the rural areas and especially among women and the uneducated. Shamanists believe in a universe where the inanimate as well as the animate object is endowed with spirits. Man's misfortune is considered to result from an improper relation with the spirits; thus, to relieve man's distress, a qualified mediator (between the world of man and the spirits), the *mutang,* is called in to perform the ritual called *goot,* through which the relationships are harmonized. There are two types of mediators: the "charismatic shaman" who becomes qualified to have close rapport with the spirits through her own psychological experience, and the "hereditary shaman" whose qualification derives from heredity, as in the case of a daughter of a shaman (2–4). About 80 percent of shamans are women.

Buddhism was introduced from China in the fourth century and spread widely. The level of its influence and official acceptance has fluctuated, often in inverse relation to the official status of Confucianism; Buddhism peaked during the 11th to the 14th centuries. While Confucianism as a rational ethical system has appealed more to the literate man, Buddhism seemed to have a wider appeal to women. Buddhism has a sophisticated cosmology and psychology, but the version popularized in Korea has been vulgarized and fused with shamanism; its more intellectual version has remained confined to a small number of scholars.

The relevance of Buddhism in the treatment of mental patients has been discussed elsewhere (5, 6).

Confucianism can be considered as essentially a rational, ethical system whose overriding concern is man's relation to society, unlike Korean shamanism and Buddhism, one of whose explicit functions has been to provide psychological help and the promise of relieving man from his misfortune and misery. The appeal of Confucianism was confined largely to literate men. Introduced from China during the early Koguryo dynasty (378 B.C.?–668 A.D.), and having attained the status of a state ideology during the Yi dynasty (1392–1910), Confucianism left a profound social and intellectual legacy. This was perhaps felt more on a conscious and explicit level than shamanism or Buddhism.

Korean folk medicine consists largely of herb medicine, acupuncture, and moxa; introduced from China, these forms of treatment are still prevalent. Even today, the large majority of potential psychiatric patients from the rural and coastal areas, and even many city dwellers who are uneducated or poor, will resort to such types of therapy.

In a largely agrarian society embedded in tradition,[1] where man was preoccupied with meeting the urgent physical and material needs of his daily life, possession of mental stamina was a necessity. But when the situation demanded, there were resources available such as shamanistic rites and folk medicine that were congruous with the people's life-style and continuous with their conscious and unconscious values. The tiny pocket of psychiatric care—part of Western medicine—remained largely alien to the majority of Koreans, except perhaps as a last resort.

Then came 1945. As Korea regained her independence from Japanese rule she was brought out of her seclusion as a "hermit kingdom" in a corner of East Asia and was thrust into the mainstream of the 20th century and into the vortex of the cold war; she found herself involuntarily divided into the South and the North. From 1945 to 1950 the mood of Korea was one of excitement, confusion, and culture shock, and turmoil prevailed. Then came the Ko-

Dr. Chang is Assistant Clinical Professor of Psychiatry, Yale University School of Medicine Department of Psychiatry, 34 Park St., New Haven, Conn. 06519, and Dr. Kim is Assistant Professor of Neuropsychiatry and Chief, Department of Psychiatry, Kyung Hee University School of Medicine, Hoekidong, Seoul, Korea.

[1] Detailed information on the historical background (7) and on sociological and anthropological factors (8) is available.

rean War, which ended in 1953. Social conditions between 1945 and 1953 were hardly conducive to healthy growth of the society; even a maintenance of the status quo required considerable effort. Following the war, large-scale emigration of Korean physicians to the United States began, and a significant number of them specialized in psychiatry. It is of interest that Koreans showed more affinity for psychiatry than physicians from other parts of East Asia. Currently, the psychiatric manpower pool in Korea is composed largely of returnees from the United States.

THE PRESENT STATUS OF PSYCHIATRY[2]

Manpower

There are 98 psychiatrists and 82 persons in psychiatric residency training in Korea. Of the 98 psychiatrists, 25 percent are affiliated with eight medical schools (five in Seoul City and one each in Kwangju, Taegu, and Pusan City); ten percent are in military service; 34 percent in private practice; 28 percent in public mental hospitals (run by national, provincial, or city governments) or administrative positions; and three percent in miscellaneous jobs.

There are 2,590 psychiatric beds, with the following distribution: the National Mental Hospital, 600; three other public hospitals, 350; 30 private mental hospitals, 1,400; and eight medical school hospitals, 240.

To become a psychiatrist, one must attend premedical college for two years and medical school for four years, followed by one year of internship and four of psychiatric residency training. After the training, a qualifying examination is given; two-thirds of the applicants are reported to pass. The training is provided at 14 hospitals (eight in medical schools, four military, one private, and one national). The stipend for trainees ranges from $75 to $110 a month.

The monthly income of practitioners generally ranges from $1,000 to $1,500, although some earn as much as $5,000. The relatively high income is possible because most practitioners operate an inpatient facility (private mental hospital) as an integral part of their practice. However, living expenses are also high. For instance, although such basics as food are inexpensive, housing is very expensive in Seoul City, where the majority of psychiatrists reside. And an automobile is increasingly becoming a necessity; both the initial cost and maintenance are perhaps double those in the United States.

Incidence of Mental Illness

Few statistics on the incidence of mental illness are available, especially in regard to the urban population. A large-scale population migration during the Korean War and a large influx into Seoul City, which grew from one and a half million to six million inhabitants in less than 20 years, make such a study difficult.

Epidemiological studies of rural farming and coastal fishing villages were made in early 1960 (9); it was estimated that 0.2 percent of the population under study suffered from schizophrenia; 0.2 percent from epilepsy; 0.02 percent from manic-depressive psychosis; and 0.001 percent from general paresis. It has been estimated that 300,000 patients need hospitalization and that 150,000 beds are required.

Hospital Facilities

The total number of available hospital beds is 2,590; only 300 of these are for patients who cannot pay. Since the public welfare and health insurance systems are conspicuously undeveloped, only the relatively well-off have access to the hospital beds.

In the past, the large extended family often functioned as an emotional as well as an economic cushion for the unfortunate relative in distress, but industrialization and the lessening of extended family ties are making such traditional aids less available. However, for those who cannot afford or will not accept hospital treatment (who in fact make up the majority), folk medicine, shamanistic or Buddhist rites, or one of the mushrooming "new religions" are readily available.

The average length of hospital stay is from three to four months and most are of less than six months; only one percent of the patients stay longer than a year. The length of hospital stay is determined less by the nature or severity of the condition than by the financial circumstances of the patient (10).

The main treatment modality with hospitalized schizophrenic patients is somato-organic: tranquilizers are often used in combination with shock treatment (11). The use of this combination, which again is largely determined by economic reasons, is aimed at facilitating early discharge. However, psychotherapy is being utilized increasingly.

Some Culturally Determined Clinical Features

The incidence of hysteria is high. For example, one study showed that 12 percent of all admissions (and 20 percent of the female admissions) to Seoul National University Hospital were for hysteria (11); the symptoms were the classic ones (12, 13). This high incidence has been attributed to the low level of medical knowledge, the traditional repression of sexuality, a shamanistic influence that facilitates projection toward the external (supernatural) being as the source of psychic conflict, and the traditional inhibition of verbalization and expressions of emotion.

The incidence of senile psychosis is low (11). This is attributed to a traditional regard for the elderly and the protective environment provided by the family.

The incidence of alcoholism and related psychosis is also low. Drinking is regarded as a facilitator of human relations; solitary drinking is frowned upon and is rare.

[2] The figures given here are based on the situation about 1970. There has been considerable further development; an estimate of about a 20-percent expansion in psychiatric manpower and facilities seems reasonable.

Further, drinking is almost always accompanied by a substantial meal.

The low incidence of drug addiction is attributed largely to strict control of the drug traffic. However, habituation to nonnarcotic drugs such as barbiturates is increasing.

The incidence of sexual perversion is low; this is attributed to rigid segregation of the sexes and the assignment of distinctly different roles to men and women from childhood (11, 14).

In regard to schizophrenia, a common symptom is a paranoid delusion; often there is a political theme such as "spy," "secret agent," "high official," etc. In women, manifestation of a thinly disguised sexual theme is increasing, reflecting conflict between the rigid traditional sexual morality (repression and segregation) and the sexual liberalism that is now being conveyed through the mass media.

Shin-Byong, a culture-bound depersonalization syndrome, often occurs in the course of a prolonged psychosomatic illness, psychosis, or psychoneurosis. The possessed person has a "revelation" (through a dream, etc.) in which he is persuaded to become a shaman. The possessor is often the spirit of a departed ancestor. With his conversion into a shaman the patient becomes "cured" of his ailment. The prevalent belief among the uneducated is that the *Shin-Byong* can be cured only through a shamanistic rite and that the cured person is obliged to become a shaman himself. The incidence of *Shin-Byong* is decreasing (2).

PSYCHIATRIC ORGANIZATIONS AND PUBLICATIONS

The Korean Neuropsychiatric Association was formed in 1945, and an official journal, *Neuropsychiatry,* has been published since 1962. Originally published biannually, it is now published quarterly. Fifty to 60 articles appear annually, and 30 to 40 papers are presented at the annual meeting of the society. A textbook of psychiatry was published in 1969 (15). Since the early 1950s a dominant interest of Korean psychiatrists has been a functional approach to mental illness, with emphasis on psychoanalysis. Lately, however, their attention has been widened to include psychopharmacology as well as other organic modalities.

There has been a recent upsurge of interest in ethnopsychiatry (2–4), notably regarding shamanism, and significant studies on the psychology of the indigenous intellectual tradition (notable Korean Confucianism, Buddhism, and Taoism) and its relevance to mental health are being carried out (5, 6).

SUMMARY AND CONCLUSIONS

Until 1945, the fact that psychiatric resources in Korea were meager was compensated for by the preventive and curative elements within the indigenous cultural tradition, namely shamanism, folk medicine (herbal, acupuncture, moxa, etc.), and the Korean version of Buddhism and Confucianism.

Since the end of World War II, and as Korea regained her independence, the political-economic situation was such that her cultural orientation shifted toward the United States. In this context, Korean psychiatry became dominantly influenced by American psychiatry, especially its functional approach. One recurrent question has been the extent to which Western (American) psychotherapy is applicable in Korea. The current opinion is that it is applicable in principle, but with technical modifications. However, further experience is necessary since the question of the relative effectiveness and clinical validation of psychotherapeutic theory is difficult to judge. A recent upsurge in the psychological study of indigenous cultural traditions and their relevance to mental health can be viewed as a healthy development.

A serious problem in psychiatry, as well as in other branches of medicine in Korea, is the inequity of the care delivery system, the undeveloped welfare and insurance systems, and the relative lack of preventive measures.

A study of the developmental history of psychiatry in Korea can be both interesting and productive, since Korea is a country where the forces of tradition and of modernization, as well as the complex crosscurrents of cultural interaction in the society at large, are likely to be sensitively reflected.

The Psychotherapy of Schizophrenia: Does It Work?

BY JARL E. DYRUD, M.D., AND PHILIP S. HOLZMAN, PH.D.

Empirical studies of the treatment of schizophrenia show the unequivocal ameliorative effects of psychoactive drugs. No comparable effects have been claimed for psychotherapy. As a result, psychotherapy has tended to be negated as a viable therapeutic factor in the treatment of schizophrenia. Yet the sophisticated drug evaluation studies are not matched by sophisticated assessments of psychotherapy. Serious methodological errors exist in the latter studies; there have been inappropriate outcome criteria, inadequate assessment procedures to measure change, unsound selection of therapists, and unclear diagnostic appraisals. The issue has been further clouded by the heterogeneous nature of psychotherapeutic interventions, comprising as they do—in contrast to the relatively simple administration of drugs—a congeries of methods, techniques, and goals. This paper examines some of the requirements for appropriate evaluation studies of psychotherapy of schizophrenic patients.

MANY A DIFFICULT QUESTION—such as the one posed here—has resolved itself into clearer focus by judicious rephrasing. The question as it appears in the title allows no clear-cut answer, brings us no nearer to fruitful understanding of the critical issues before us, and indeed may even be counter-productive—all for reasons of the ambiguities in the words "psychotherapy" and "schizophrenia" and in the vagueness of the meaning of "Does it work?" For most clinicians, the two key words, schizophrenia and psychotherapy, have stimulated confusion in that one man's schizophrenia is another man's schizophreniform psychosis, and in most researches the "Does it work?" challenge conjures up kaleidoscopic visions of outcome criteria merging into outcome criteria. What does "work" mean?

We therefore choose to begin by restating the question in a way that permits answers that are less representative of partisan views and more indicative of the current state of our knowledge. We hope the clarity that will emerge will be regarded as helpful and not merely as obsessional hair-splitting. In this brief paper, then, we will first attempt to clarify the question by considering each of its elements, and then go on to try to answer the challenge from the available data.

Read at the 125th annual meeting of the American Psychiatric Association, Dallas, Tex., May 1–5, 1972.

The authors are with the Department of Psychiatry, University of Chicago, 950 East 59th St., Chicago, Ill. 60637, where Dr. Dyrud is Professor of Psychiatry and Dr. Holzman is Professor of Psychology and Psychiatry.

PSYCHOTHERAPY

For the sake of consistency we will confine ourselves here to speaking of one-to-one treatment, but with the clear understanding that this form of psychotherapy is a deliberate and specialized pursuit arising out of the patient's broader supportive milieu in which a variety of other psychosocial events occur. It is well to bear in mind that this milieu has always been with us. It operates on intensive psychotherapy wards just as certainly as on wards labeled "drug treatment only." It was the therapeutic agent in "moral treatment" (1) in the last century. It had its burst of enthusiasm as a therapy following the second World War and was then almost totally eclipsed by the advent of the phenothiazines, with their development of more precise measures of effectiveness. No one knew what the central effects of the drugs were, but research design was easy. Control and comparison groups could be marshaled; randomization, double-blind, and cross-over designs added elegance to the evaluative process. Another revival of interest in the milieu is now upon us as behavior-modification techniques make the milieu operate in ways that are more observable and controllable (2). Change indicators in behavior have become easy to specify, although the issues of generalization to the noncontrol and posthospital environment are still to be investigated. All of this is to say that we have hopes now of specifying more of the "nonspecific" therapeutic events in a patient's career.

One of man's characteristics seems to be his need for explanations (3). Our efforts to account for events are usually focused on a single aspect, called the "essential ingredient" of a transaction. Much of the disputation in our field is concerned with elevating one or another aspect of the total care of the patient, such as medication or psychotherapy, to this status, with a corresponding neglect of other factors operating in the patient's milieu.

As far as individual psychotherapy is concerned, there seems to be only a small gain from restating a view well known to psychiatrists: psychotherapy is not a unitary process. Yet for the sake of our argument let us repeat that psychotherapy is unlike most other therapeutic procedures; in surgery, for example, accurate diagnoses are possible and, on the basis of those diagnoses, rational treatments consisting of clearly defined procedures can be begun. In contrast, psychotherapy does not consist of a definite set of operations and the essence of the procedures is still a matter of personal preference, bias, and lively controversy. There is no "dose" of psychotherapy. The procedures subsumed under the "psychotherapy" label include the classical psychoanalytic procedure, those based upon it, and those emphasizing only understanding or affect-expression or modification of observable behavior by operant techniques—to name only a few of the occupants of this psychosocial Tower of Babel.

The people who present themselves for such treatment also comprise a heterogeneous group, obviously not suffering from a single, reliably diagnosed condition. Rather, a range of human problems is presented, including situational crises, neurotic conditions, character difficulties, and psychoses. Further, the people who present themselves for help from psychotherapists differ among themselves in striking ways: intellectually, characterologically, socioeconomically, culturally, in age, and in hosts of life experiences.

We could expand the list of complications in the use of the word "psychotherapy," but we will mention only one more: the enormous range of differences among psychotherapists. Whereas the technical operations of surgical procedures can be taught, and variations are a matter of general codification, psychotherapists can rarely be taught the ingredients of most psychotherapies: empathy, compassion, tact, timing, mutative intrusiveness, and interest in the various kinds of human problems that patients present. The therapist himself is therefore a crucial variable in the psychotherapeutic relationship. This is true not only insofar as orientation to psychotherapy is concerned, but also insofar as the kind of person the psychotherapist is.

From these considerations it would seem that the first element of the question should be changed from "psychotherapy" to "some psychotherapeutic procedures practiced by some psychotherapists."

SCHIZOPHRENIA

The word "schizophrenia," like psychotherapy, is an example of what may be called the "fallacy of misplaced singularity." Bleuler (4) of course spoke of "the group of schizophrenias," by which he recognized the heterogeneity of conditions subsumed under the label. The conditions include the clear-cut process schizophrenias, insidious in their onset in early adolescence and proceeding ever more malignantly into dementia; the oscillating, phasic schizophrenic conditions; the rigid, litigious paranoid schizophrenic processes that appear in the third and fourth decades of life; and the acute schizophreniform psychotic episodes, from which some patients apparently recover completely, as Laing (5) and Menninger (6) have described, and from which many more patients never reach a *restitutio ad integrum*. There are nonpsychotic conditions, too, that we label schizophrenic: the so-called latent schizophrenias, incipient schizophrenias, ambulatory schizophrenias (7), and even remitted schizophrenias.

Much of the research data emerging from family and genetic studies—e.g., those of Heston (8) and of Rosenthal, Kety, Wender, and Schulsinger (9)—point to even broader areas of concern than the area of syndromal descriptions; these studies suggest a spectrum of conditions that include people with severe neurotic symptoms and even those without pathology but who show a distinctive, novel, creative outlook on reality. In some studies it has been found that subtle evidence of thought disorder exists in a setting of normal social, occupational, and family behavior. From these studies perplexing questions about etiology arise: Are the serious schizophrenias to be considered etiologically related to the neuroses? That is, if one accepts a conflict etiology of neurosis, such as that presented by Freud, can one fit the schizophrenias into such a psychoanalytic model? Or, if one accepts such a thoroughgoing empirical model as the one Skinner (10) has outlined, in which all behavior is a learned outcome of their consequences, can one fit the schizophrenias into such an operant model?

It would appear that the second element of the question has resolved itself into "the schizophrenias," and has implicated an etiology that may be far more complex than the conditions for which the usual psychotherapies were developed. This position does not disavow the etiological importance of learning, family strains, and intrapersonal conflicts. Rather, with our expanding knowledge of genetic, biochemical, and quasi-stable personological factors, we prefer to think of all of these factors as "contributory" or "necessary etiological conditions" rather than specifically or uniquely causal in the schizophrenias. In keeping with Adolf Meyer's psychobiological approach (11), we recognize that a crucial diagnostic task is the assessment of the relative contributions of familial, genetic, conflict, biochemical, psychological, and sociocultural factors in order to be able to aim a treatment program at its proper target. For it would seem that in the severe, disintegrated schizophrenic conditions a plurality of therapeutic methods would be called for, simultaneously or sequentially, rather than reliance on one technique alone. Thus the early treatment steps may well be focused on reducing the ambiguity of the environment in an operant conceptual framework, to be followed by

more stress on the therapeutic relationship, perhaps in conjunction with phenothiazine administration.

DOES IT WORK?

We have already alluded to the ambiguities in this question. The "it" is really "they," and by "work" we need to specify more precisely the outcomes we expect or hope for in the various kinds of schizophrenic conditions. If the expectation is merely discharge from a hospital, the overwhelming weight of evidence presents psychotherapy as having very little effect (12). The phenothiazines alone claim clear justification for an ameliorative effect, and even those original generalizations are having to be revised to take into account the diversity of the schizophrenias. Goldstein (13), for instance, suggested strongly that nonparanoid schizophrenic patients with good premorbid adjustment may be adversely affected by phenothiazines. Overall, however, research suggests that psychotherapy either alone or in combination with the phenothiazines contributes no significant reduction in the hospital stay of schizophrenic patients. We do not challenge the validity of these findings. A critical issue, however, is the nature of the criterion of outcome as it relates to the process of treatment. The criterion for discharge from a mental hospital may have little relation to much else about a patient except his greater manageability. Many other aspects of the patient's condition may not be considered in this decision. For example, relevant issues should include: 1) whether he can gainfully support himself and his family, or, if the patient is a woman, whether she can return to her specific occupation, whether this be gainful employment or homemaking; 2) whether he can be reintegrated into the community; 3) whether there can be developed self-generating behavior that brings a significant pleasurable return (this would include, for younger patients, help with career lines, resuming school, occupational training, and the learning of social skills).

It is obvious, after short reflection, that the criterion of discharge from the hospital is not one that favors the identification of psychotherapy as a viable therapeutic tool. Not the least of the reasons for its inappropriateness is the fact that psychotherapy hinges on a subtle yet powerful factor of trust—a feeling of respect, expectation, and hope that the patient develops. These attitudes take time to form and more time to nurture. The therapist, whatever his persuasion, attempts to break into the isolation, loneliness, and (for many patients) the terrifying world of bewildering instability to become a stable figure on whom the patient can rely for advice, direction, interpretation, or mere presence. Therefore, one gets another perspective on the effectiveness of psychotherapy if one uses the rate of relapse as the criterion of outcome.

While we await the follow-up data from the Camarillo study (12), the Hogarty-Goldberg (14) results strongly endorse a psychotherapeutic contact as having a significant effect on holding down rehospitalization rates. The psychotherapy employed in that study was a variant of avuncular guidance called "major role therapy." It was essentially vocational counseling and social casework in the context of firm interpersonal bonds. The statistics are instructive: At the end of 12 months after discharge from hospitals, 72 percent of the placebo-alone group relapsed; 63 percent of the group receiving placebo plus major role therapy relapsed; 33 percent of the phenothiazine-alone group relapsed, and 26 percent of the group receiving the drug plus major role therapy relapsed. Clearly, major role therapy helped reduce relapse rates more than drugs alone did. But even more striking is the fact that the principal effect of the major role therapy began to show itself only after seven months, particularly in combination with maintenance drug therapy. Individual differences among relapsers and nonrelapsers point to the necessity for further defining groups of patients along relevant demographic, cultural, clinical, and personologic characteristics in order to assess which patients will significantly profit from the particular brand of psychotherapy under study.

The Hogarty-Goldberg study, then, is consistent with the view that psychosis is a phase of a schizophrenic adjustment which requires resolution by the most efficient means possible. Following this phase, a period of habilitation may be profitably introduced for some patients. For which patients the psychotherapeutic phase is required is a matter to be left to systematic research. There are many acutely schizophrenic patients who improve dramatically regardless of what we do; there are those who remain psychotic in spite of what we do; and there is a group of patients for whom it matters very much what we do. The question remains open as to what treatment is appropriate and adequate for which patients. What is missing from our research armamentarium is the use of sensitive instruments to detect the myriad intrapersonal changes that occur with and without psychotherapeutic intervention. There is no a priori reason to assume that the fantasy meaning attached by the patient to events in reality can be influenced only by one-to-one psychotherapy. Other clarifying interactions can occur on the ward, medication *can* clear cognition, and direct behavioral intervention as an access route to revamping symbolic processes remains a real and unassessed possibility.

A small number of dedicated psychotherapists who have devoted many years to the treatment of small numbers of patients have reported sporadic success with their schizophrenic patients; these include Fromm-Reichmann (15), Searles (16), Wexler (17), Will (18), Sullivan (19), and Ekstein (20). While no systematic evaluation of the schizophrenic process was attempted by these gifted people, the length of time and the great absorption required for this kind of intensive procedure would make it unfeasible for use with the vast numbers of people diagnosed as schizophrenic. The theoretical rationale of this approach to psychotherapy assumes that the schizophrenic condition, like a symptom neurosis, is a compromise outcome of unconscious conflicts, resolvable with less pain to the person by psychoanalytic exploration. Without denying the role of internal conflict in schizophrenic disorganization, we would opt for relegating to it a contributory significance, secondary to what Freud called a "narcissistic disturbance," and translating

it as "structural and developmental deviations in respect to one's self-feeling." Nonpsychological variables, we believe, must be recognized in this context, and to that extent pharmacologic treatment should be considered as part of the treatment program, particularly when psychotic symptoms are manifest. Since the investment of time is so great in this particular kind of psychotherapy, we would endorse it as a technique for research into the schizophrenic experience rather than as an efficient therapeutic agent.

In a number of studies evaluating the relative merits of somatic treatment versus psychotherapy, it would seem that a principal reason that nonpsychological treatments such as drugs are consistently superior to psychosocial measures is that the special target of each therapy has not been recognized. Drugs will reduce thought disorganization, quiet an unruly and excited patient, or mobilize a withdrawn patient. It remains for psychosocial interventions to teach and to train, to reassure and to raise self-confidence, and to help with skills for living that some patients may never have learned or may have learned badly. These interventions take time to become effective, but when they do there is some evidence, of which we need more to be certain, that less medication is needed to maintain a patient in a stage of remission.

NEED FOR REVIEW OF PSYCHOTHERAPY STUDIES

In the early 1960s the field of the biochemistry of schizophrenia received a searching examination by Kety (21, 22), who found many of the studies to be methodologically deficient. He seriously questioned unwarranted conclusions. This review had the effect of improving the standards of many of the studies and ushered in a new era of biochemical advances with respect to schizophrenia. The field of the psychotherapy of schizophrenia could well profit from a similar intensive review of studies. That review would surely point to several of the issues raised in this paper. First, the nature of the outcome criteria: What is it that we expect psychosocial interventions to accomplish—in which patients, at what stage of the disorder, by what kinds of therapy? Second, what is the role of intrapsychic conflict resolution in the treatment of the schizophrenias; at which stages of the disorder would it seem irrelevant, and at which stages would it seem helpful to introduce such a therapeutic regimen? Third, what is the role of teaching living skills and to which patients? And fourth, what qualities of patient and therapist should be matched? This last point, one not developed in this paper, impresses us as having important consequences for effective treatment. The Whitehorn-Betz categories of group A and group B therapists (23) began the search into this area; we need now to probe further into this question, including the cognitive-stylistic organization (24, 25) of both patient and therapist to study its effect on various outcomes.

The Psychotherapy of Schizophrenia: An NIMH Program

BY RAYMOND J. FRIEDMAN, M.D., JOHN G. GUNDERSON, M.D., AND DAVID B. FEINSILVER, M.D.

The authors discuss a current NIMH program whose purpose is to study the empirical knowledge of senior psychotherapists who treat schizophrenic patients and to translate this knowledge into potential research data. Such data, it is hoped, may add a new dimension to the treatment of the schizophrenic patient, which currently emphasizes the use of drugs. Thus far, the five groups of therapists who comprise the program have agreed upon a working definition of schizophrenia, the qualities of patients and therapists who do well in therapy, and the task of the initial treatment phase.

IN THIS PAPER WE WISH TO DESCRIBE the status of an NIMH experimental pilot program that has been in operation for one year and whose purpose is to examine the empirical knowledge of senior psychotherapists who specialize in the intensive long-term treatment of schizophrenic patients. The major goal of this venture is to translate the often intuitive notions of these psychotherapists about the schizophrenic process and its treatment into variables that can be reliably observed and into hypotheses that can be tested.

One assumption that underlies our renewed interest in and attention to this domain of treatment is that current therapeutic efforts, with their strong emphasis on drug treatment, have not significantly affected the long-term social adaptation of schizophrenic patients (1). It is hoped that the era of warfare between proponents of the various therapeutic modalities is at an end, especially the chronic feud that has existed between those schools advocating psychotherapy and those espousing drug treatment, each to the exclusion of the other. As May (2) has stated, drugs may be "the single most powerful and economic treatment for schizophrenic patients." While the phenothiazines represent an undisputed addition to the therapeutic armamentarium, perhaps we hope for the impossible if we expect a drug to alter the myriad of social and interpersonal problems and deficits in learning that beset schizophrenic patients.

Read at the 125th annual meeting of the American Psychiatric Association, Dallas, Tex., May 1–5, 1972.

At the time this work was done, Drs. Friedman and Gunderson were both with the Clinical Research Branch, Division of Extramural Research Programs, National Institute of Mental Health, Rockville, Md., where Dr. Friedman was Assistant Chief, Depression Section, and Dr. Gunderson is Assistant Chief, Center for Studies of Schizophrenia. Currently, Dr. Friedman is in private practice at 11665 West Olympic Blvd., Los Angeles, Calif. 90064. Dr. Feinsilver is a Staff Psychiatrist, Chestnut Lodge, Rockville, Md.

Our impression is that the enthusiasm generated by the discovery of the phenothiazines, when coupled with the new, sophisticated studies of the biological and genetic aspects of schizophrenia, has stimulated hope for the future but has also spawned a measure of despair in the present by overshadowing psychosocial modalities. The question of whether individual psychotherapy with schizophrenic patients is efficacious remains in dispute. Despite the gloomy nature of the conclusions drawn from most of the existing outcome studies (3), therapists working with schizophrenic patients remain convinced that their ministrations are effective and produce profound changes in the patient's internal state, as well as in his rapport with the environment.

The second assumption upon which the current endeavor rests is that certain therapists working with particular patients do effect significant and lasting changes. Strupp and Bergin reached a similar conclusion concerning the individual treatment of neurotic patients, and both Strupp and Bergin (4), as well as Robbins (5), emphasized the need to study the work of experienced psychotherapists—a deficiency of most current outcome research.

There are several possible methods of employing the expertise of senior psychotherapists in research. Perhaps the most obvious and direct approach, although one fraught with great difficulty, is to employ gifted senior clinicians as the therapists in outcome research. A second approach, which we believe represents a more modest goal and an essential first step in the direction of eventual outcome research, is to engage senior clinicians in specifying the various dimensions of the often nebulous term "psychotherapy." Only when we begin to specify which type of therapist working with which type of patient with what specific techniques and in what specific settings will we have identified enough of the critical variables to begin to initiate relevant outcome research.

Senior clinicians as a group have been distant and at times even hostile to research endeavors. By inviting them to discuss the therapy they do and to keep in mind its potential for research, we hoped to address another major problem confronting the field of psychotherapy research, which was highlighted by Strupp and Bergin (4). They noted that "thus far research in psychotherapy has failed to make a deep impact on practice and technique." We believe that one reason for the limited feedback between psychotherapy research and clinical practice stems from the fact that, somewhere in the process of translating the techniques of successful therapy into variables that qualify for rigorous research, clinical relevance is compromised and sometimes totally lost. We believe that

one method of strengthening the links between research and clinical practice is to involve the experts, the treaters, in the very process of research design.

As a final note of introduction, we should emphasize that this venture has been undertaken with somewhat guarded optimism, for as Rosenthal (6) has pointed out: To ask therapists to describe what they do is analogous to asking artists to explicate their sources of inspiration and techniques of execution—a notoriously difficult task.

THE APPROACH

Five discussion groups have been established in the following locales: Washington, D.C., Chicago, the New England area, San Francisco, and Los Angeles. The group members[1] have met on the average of twice a month during the past year. A group is composed of five or six senior psychoanalysts, each averaging approximately 20 years of experience in treating schizophrenic patients. At the initiation of this program we approached psychoanalysts because of their well-known and almost exclusive interest in long-term intensive individual psychotherapy.

Although no systematic formal effort has been made to assess the theoretical leanings of the various group members, we can, with some assurance, state that a broad spectrum of theoretical positions is represented. Clinical experience, a reputation for success in treating schizophrenic patients, and compatibility as a group member were the criteria generally used for inclusion in the program; no attempt was made to balance the groups by theoretical stance.

The NIMH mandate to each group was deliberately presented in a broad and often hazy manner in order to facilitate group autonomy and to allow each group to pursue its own interests. At the inception of the program no obligation was negotiated with group members, and none was intended beyond the first meeting. Thus, the involvement of these men in subsequent meetings represented their continuing interest and not the fulfillment of a prearranged contract with NIMH. In order to facilitate and to provide a launching pad for discussion during the first phase of the project, we distributed the following questions to each group prior to its initial meeting: 1) How do you operationally conceptualize the nature of the schizophrenic's difficulties? 2) How do you characterize the kinds of schizophrenic patients who profit or fail to profit from individual psychotherapy? 3) What are the essential characteristics of therapists who work well with schizophrenic patients?

[1] The participants include: Drs. Marvin Adland, Nathaniel Apter, Gerald Aronson, Jarl E. Dyrud, Stanley Eldred, David Feinsilver, John P. Fort, Beatriz Foster, Alfred Goldberg, Ralph Greenson, Roy Grinker, James Grotstein, Philip Holzman, Lawrence Kayton, Arthur Malin, Herbert Meltzer, Clarence Schulz, Daniel Schwartz, Elvin Semrad, Helm Stierlin, Milton Wexler, Otto Will, Emanuel Windholz, and Lyman Wynne.

THE RESPONSE TO QUESTIONS

Working Definition of Schizophrenia

Mosher (7) has argued that, in research project protocols, the inclusion of a working definition of schizophrenia which concerns psychosocial treatments of the illness will enhance the prospects of future replication of findings. Surprisingly, the task of defining the disorder produced the least amount of disagreement among the groups. A composite definition, based on the responses of the group participants to the first question, follows.

> Schizophrenia is a disorder of ego functioning caused by developmental, parent-child experiences (which may include biological-constitutional elements) which results in a deficit in the ability to separate out and maintain accurate internal mental representations of the outside real world. This deficit, in turn, causes the production of restitutional symptoms (delusions, hallucinations) which are most prominent when the individual is confronted with the stresses of developing independent, mature, trusting adult relationships.

Amendments to this definition would include the emphasis: 1) that individuals falling under this rubric are in reality not *that* qualitatively different from "normals"; 2) that it is primarily the mother-child relationship which is disturbed; and 3) that this definition, while implying homogeneity, should recognize the heterogeneous nature of those falling within it.

On examination of the definition the following observations seem noteworthy.

1. Except for the nature of the possible deficit and for the resulting restitutional symptoms, this definition could apply to other categories of psychopathology.
2. There was no rush to advocate a strictly environmentalist approach to the cause of schizophrenia. In fact, there was frequent acknowledgment that some poorly defined constitutional or biological factors may be at work in the schizophrenic. The clinician-participants did not view the possibility of a genetic predisposition as incompatible with their pragmatic approach of doing whatever was possible.
3. The concept of a schizophrenic inability to maintain internal mental representations was articulated in a variety of ways by group members. Although the participants described many different aspects of the same phenomena, the differences in their descriptions ultimately seemed to be more semantic than real.
4. The basic schizophrenic psychopathology is at least in part a derivative of early primary relationships to parents and the conflicts in those relationships that have led to primitive ego functioning.

Patient Characteristics

The following discussion focuses on patient variables that are hypothesized to relate positively to successful prognosis in therapy:

> Schizophrenic patients who tend to profit the most from individual psychotherapy are young and intelligent (IQ above low normal), "reactive," and present during their first

break in an acute manner. They have a past history of achievement at work and in other creative activities, as well as some success in interpersonal, especially heterosexual, relationships. They are motivated and tend to experience "pain" or the sense of a "struggle" and definitely see themselves in need of help. They often appear to be striving actively for higher levels of functioning, and exhibit some degree of the following capacities: self-observation, problem solving, integrating experience, self-control and the ability to delay gratification.

A history of hospitalization as an independent variable (that is, as independent of chronicity) was not felt to be highly related to outcome. In addition, the depth of regression (especially during the acute phase) was not considered a significant prognostic variable.

We can only speculate about the rather pedestrian quality of this summarized discussion concerning patient variables and offer the suggestion that perhaps the strong emphasis placed on therapist characteristics as being critical for positive outcome overshadows a more in-depth consideration of patient characteristics. However, it may well be that there is simply nothing radically new or different to be added, even by these distinguished clinicians, to the existing research literature in this area (8, 9).

Therapist Characteristics

During both preliminary and subsequent meetings, the subject of therapist characteristics received considerable attention from all of the groups. Two general characteristics repeatedly emerged from their discussions. The first concerned the therapeutic zeal necessary for long-term intensive psychotherapy with schizophrenic patients. This characteristic represents a deep "personal" need on the part of the therapist to help this particular type of patient. There was recognition that such a sense of mission may indeed represent a "rescue" fantasy or a desire to play God. Thus, while the virtual necessity of this "near-driveness" was recognized, the stipulation was made that such a drive be well integrated into the therapist's personality so that it is reasonable and manageable.

The second primary constellation of characteristics associated with therapeutic success with schizophrenic patients and also correlated with the optimism and enthusiasm necessary for this type of work concerns the ability to tolerate extreme frustration, despair, helplessness, and often lack of progress in therapy. Lest we foster the image of the therapist as a paragon of perfection, it should be noted that group consensus existed that therapists who treat schizophrenics have, in general, suffered painful life experiences which tend to render them "honest," "real" people who have struggled to attain a strong sense of identity. Perhaps the suggestion of omnipotence that threads throughout the discussions relates not so much to the perfection of the therapist's personality as it does to his awareness of and attempts to master his imperfections, which will be so severely challenged by his schizophrenic patients.

Overly perfectionistic and excessively critical people will tend to be among those who continually fail in attempts to treat schizophrenic patients. While perseverance and even a sense of being driven is necessary for success, therapists who are motivated by a guilt-ridden feeling of omnipotence seem doomed to failure, as are therapists who tend to view schizophrenic patients as superhumanly precious or fragile.

The personality characteristics of the therapist have emerged as the set of factors that are hypothesized to be the primary determinant of success or failure in intensive therapy; issues of technique, while important, have not been accorded so high a status.

The Initial Phase of Therapy

The groups were unanimous in identifying that the primary task of the initial phase of therapy with the schizophrenic was the establishment of "contact," a term that defies exact definition but refers to "attachment behavior" and a "trusting relationship." While establishing contact, offering the patient the possibility of being understood, and beginning to develop a relationship that will allow him to view the therapist as a constant, reliable, and predictable person, many believe that the therapist is also called upon to exhibit a number of behaviors, including caring for and about the patient, attempting to understand him, fostering dependency, being reliable, and, above all, appearing as a real person to the patient. The therapist will often be called upon to assume the role of an auxiliary ego, helping the patient to deal with numerous daily problems of a here-and-now nature and to correct his misperceptions of the world.

SUMMARY

We have described the NIMH program on the psychotherapy of schizophrenia and the principal areas of agreement among participants in five geographically based discussion groups about an operational definition of schizophrenia, the qualities of patients and of therapists who do well in psychotherapy, and the initial stage of treatment. It is understood that this presentation is a partial account of the broad range of topics discussed by the groups and, in particular, has not attempted to deal with topics the groups are currently exploring in depth. We are already certain that this endeavor has allowed for many meaningful exchanges among group members and that the yield from this program will certainly include an enriched perspective on the finished and unfinished business of this field.

Controversies About the Psychotherapy of Schizophrenia

BY JOHN G. GUNDERSON, M.D.

The author discusses the current controversies over the psychotherapeutic treatment of schizophrenics that have come out of an NIMH program involving experienced clinicians. The controversies concern where to focus content, what techniques to employ, and what theories can be derived from intensive psychotherapy with schizophrenic patients. He concludes that studies of interactional variables and greater communication among clinicians are required to facilitate an understanding of what the therapeutic effects of such psychotherapy may be.

CONTROVERSIES HAVE EMERGED among the participating senior therapists [1] in the NIMH-sponsored project on the psychotherapy of schizophrenia (1). These controversies reflect the state of the art in 1972, and this paper will attempt to cite and explicate them.

Practically everyone has strong opinions about whether individual psychotherapy is an indicated treatment for schizophrenia and, if it is, what form the psychotherapy should take. Research attempts to answer these questions have provided incomplete solutions (2). Since all of the participants in the NIMH program advocate the individual, psychoanalytically oriented psychotherapy of schizophrenic patients, the controversies described here do not concern efficacy but, rather, what kind of intensive psychotherapy should be given and for what reasons.

The three areas that the program participants found controversial were: 1) focus (What? What is the area of principal investigation and discussion in the interviews?); 2) technique (How? What methods does one employ to pursue the psychotherapeutic goals?); and 3) theory (Why? What is the rationale for the treatment approach one employs?). It is understood that the positions described here are polar extremes that neither necessarily reflect the mainstream of thinking on these topics nor represent positions that are rigidly adhered to, even by those who recommend them. The dichotomies in approach are often not mutually exclusive. The debate is more frequently one of emphases, priorities, or sequence.

FOCUS

The controversies over focus have concerned the initial stage of psychotherapy. Differences in approach can be seen in terms of what time parameters in the patient's life and what differing ego structures the therapist addresses in the initial phase.

Time Parameters

Some therapists focus on the patient's past, others on the immediate present, and still others on the future.

Those whose focus emphasizes the past would begin by asking the patient, "What happened?" This approach emphasizes the importance of integrating the precipitating circumstances (3, 4). The therapist sees the patient's distortion and projection as avoidance techniques and asks him to remember his painful, but real, life crises. It is necessary for a patient to recognize him-

Read at the 125th annual meeting of the American Psychiatric Association, Dallas, Tex., May 1–5, 1972.

Dr. Gunderson is Assistant Chief, Center for Studies of Schizophrenia, Clinical Research Branch, Division of Extramural Research Programs, National Institute of Mental Health, 5600 Fishers Lane, Rockville, Md. 20852.

The author wishes to thank the participants in the NIMH psychotherapy program and particularly Drs. Stanley Eldred, Alfred Goldberg, and Loren Mosher for their help in preparing this paper.

[1] The participants include: Drs. Marvin Adland, Nathaniel Apter, Gerald Aronson, Jarl E. Dyrud, Stanley Eldred, David Feinsilver, John P. Fort, Beatriz Foster, Alfred Goldberg, Ralph Greenson, Roy Grinker, James Grotstein, Philip Holzman, Lawrence Kayton, Arthur Malin, Herbert Meltzer, Clarence Schulz, Daniel Schwartz, Elvin Semrad, Helm Stierlin, Milton Wexler, Otto Will, Emanuel Windholz, and Lyman Wynne.

self in terms of his past and to see his present life as a continuum of that experience.

Other therapists doubt whether many schizophrenic patients are aware of their precipitating crisis or are willing to deal with it early in treatment. If not, they then suggest that the crisis must be reexperienced and worked through in relationship to the therapist. Still others see in this approach the danger of the therapist imposing too much of his own theory and too many of his own expectations on the patient, thus not following the patient enough.

The second approach, i.e., the present, would address a different question in the initial phase: "What are you experiencing?" This draws the patient's attention to his immediate reality and emphasizes the importance of his interaction with the therapist in ultimately coming to understand himself. Advocates see this process as critical in helping patients define their psychological (5, 6) and biological (7) self. This approach would directly take up the patient's feelings and their connection with the therapist. An effort would be made to understand the function served by the patient's operating defenses. This process might be likened to that used in ego or character analysis. Opponents to this approach say it does not address the patient's presenting psychopathology as a reaction but as part of his usual personality.

The third orientation would focus on the patient's future. The question asked here would be: "What do you want for yourself?" This question appeals to the patient's need to make decisions, to plan, and to organize. It draws the patient's attention to the aimless course his life has taken and to the maladaptive aspects of being psychotic (8). Proponents (9, 10) point to the antiregressive function of this approach and emphasize the importance of supporting the patient's development of competence and sense of efficacy from using problem-solving capacities (11). However, this approach seems to be vulnerable to the criticism that internal satisfaction depends on more than leaving home, being competent, and pursuing what one wants; that is, it depends on interpersonal relatedness. Being competent and efficacious may only be of use insofar as patients are rewarded by being loved.

Reality Versus Fantasy

Another issue regarding focus is how much attention should be paid to dreams and fantasies and how much to realities. The real-life approach views the schizophrenic's dreams and fantasies as avoidance techniques in one who is already too prone to avoid and distort what is real. According to this view, the schizophrenic is aided by more structure (being reminded of the discrepancy between reality and his fantasies and dreams) and by the therapist's role as a reality anchor (12). This contrasts with the Jungians (13) and with the following statement made by one participant in the study groups: "To really understand my schizophrenic patients, I need to understand their dreams and fantasies and spend a good deal of the analysis exploring the meaning of these." In the reality approach such an emphasis on fantasies is criticized for its danger of providing intellectual depth without the practical, reality-based connectedness that improves social adaptation.

Affects

Many therapists feel that schizophrenic disorganization is frequently a regressive response from intolerable affects (14). Opinions vary, however, as to exactly what affects the schizophrenic patient primarily needs help learning to deal with. Some clinicians see the schizophrenic's primary difficulty as recognizing and managing his aggression and its affective derivative anger (15, pp. 151–152, 16). By encouraging the patient to express anger directly they might avert the need for projection and eventually modify basic concerns about omnipotent destructiveness that are accentuated when loss is encountered. There is some research which supports the idea that therapists who focus on aggression tend to have better results (17).

Other therapists focus on the patient's need to remember the pain involved in the loss itself. This requires the patient to recognize what was positive or loved in the relationship that is now no longer available and is being missed (18). These therapists emphasize the schizophrenic's failure to acknowledge warmth, closeness, and pleasure. The primary affect called upon is sadness, and this process is not dissimilar to mourning. Along this line Searles (19) has concluded that the hateful expressions he chronicled in his early writing are basically "subsidiary to love" and "that such an ugly emotion as vindictiveness is basically a reaction against such positively-oriented emotions as separation, anxiety, and grief."

TECHNIQUE

The two major controversies about technique concern how one interacts with the schizophrenic patients.

Exploration Versus Relationship

The process of exploration might be described as a mutual patient-therapist effort to investigate and to understand the causes for the patient's dilemma. In general it is felt that this achievement will allow change, growth, and improvement. The therapist's ability to maintain objectivity in his observations of the patient is considered important. The relationship that develops between the patient and the therapist is viewed as necessary for the investigative task but not as primarily therapeutic itself.

There are therapists, however, who feel that exploration is less valuable with schizophrenics than with other types of patients. The emphasis on investigation, they believe, implies that the schizophrenic's problems are predominantly intrapsychic and does not give proper weighting to their interpersonal origins. These therapists instead emphasize the development of a "real" relationship (20) with their schizophrenic patients. In this view the therapist's role value is less one of objective inquirer and more one of subjective participant. His consistency and concern facilitate internalization (21). It is the experience of trusting and being cared about that

causes the patient's previous distrust to diminish and his low self-esteem to improve. The growing closeness of this relationship, then, provides an ego corrective experience.

Those who feel exploration is the primary vehicle of change believe that a trusting relationship is developed only after the patient is able to see what interferes with his getting close. Such a relationship is fostered by the therapist's active interest in having the patient share what he has avoided either by his telling the therapist or by the therapist's analysis of the patient's defenses against such closeness. In any event, the relationship develops as a result of the investigative process, and its importance exists predominantly—or only—in its usefulness in allowing further exploration. A third position, perhaps somewhere between the two, emphasizes the importance of investigating the ongoing relationship (22).

Closely related to this discussion of the relative importance of exploration and relationship in therapy are issues regarding the function of the therapist's interpretations, the proper use of support, and the ideal amount of activity and structure that the therapist should provide. Complaints have been registered that interpretations can be harmful because they are experienced by patients as assaults and may lead to further regression in that schizophrenics need to repress more, not less (12, 23, 24). On the other hand, some consider that supportive techniques underestimate the patient's strengths and prolong treatment. In a similar way, too much activity by a therapist is considered to carry the risk of imposing too many of one's preconceptions and demands on the patient, while its opposite, impassivity, is criticized for encouraging projection and increasing separation. Again, as with the other variables, the two sides to these issues are not incompatible, and invariably the advocates for either technique are doing more of the other than they at first acknowledge. Hence, these debates may seem more clear-cut in theory than they do in practice.

Regression

Perhaps more than any other topic in the psychotherapy of schizophrenia, regression has become an emotionally charged area of disagreement. Signals expressing the extent of these feelings can be seen in the rhetoric opposing camps use to describe each other's treatment. In a more positive sense each point of view can present a consistent approach with a persuasive rationale.

Those who are permissive and accept the patient's psychotic regression see him as recreating the unresolved infantile disorder that must be lived through and grown out of in order to attain a stable higher level of ego integration. The unfolding of a primitive transference to the therapist and the formation of a symbiotic relationship requires the therapist's permissive acceptance. The resolution of this symbiosis is a process of self-object differentiation by which the patient leaves the previous level of object relations and develops true autonomy.

Therapists who favor active interventions against regression, which might include structured milieu, maintaining contact with the family, lending support to defenses, and sometimes ataraxic drugs, stress the importance of the patient's using his ego strengths in the service of integration. Too much disorganization and primary-process thinking make working together with the patient impossible. While the therapists in the NIMH program were uniformly hesitant to attribute much lasting benefit to drugs, for some therapists the drugs do play a helpful adjunctive role to psychotherapy by compensating a patient to a point where his talk is coherent and he is able to tie his affect to his life experiences.

Without attempting a facile reconciliation it seems that, at least in part, this controversy derives from the fact that therapists who work in long-term private residential treatment centers have had little experience with the advantages of limiting regression, while those who do psychotherapy in other institutional frameworks have rarely had the opportunity to observe the advantages of uninterrupted regression.

THEORY

There are substantial areas of theoretical disagreement that include both the conceptualization of the basic schizophrenic problem (unstable introjects versus affective intolerance) and the source of this problem (deficit or defense).

Many contemporary psychotherapists have observed the central significance of problems of separation in schizophrenics (18, 21, 22, 25). The regression to primitive thinking and narcissistic defenses is initiated by the intrapsychic reaction to the loss of or separation from a person the schizophrenic has been attached to. The nature of this reaction may be considered to reflect the loss of internal objects or ultimately a failure to tolerate certain affects.

To expand on the latter point first, at the time of the separation the schizophrenic experiences bodily affects toward the important other person. This affective experience is not integrated either because of an inability to formulate or to make sense of it (22) or because it is consciously or unconsciously associated with early unintegrated catastrophic experiences of rejection or failure. It is the expectation of failure involved in acknowledging positive attachments that makes warm affects particularly frightening. This, plus the schizophrenic's capacity for dissociation, eventually leads to the flight into psychosis from the affective accompaniments of loss. Clearly an implication of this theory is that therapists must be willing to tolerate strong affects and to help the patient experience affects more fully.

An alternative conceptualization of this process also emphasizes the importance of loss but sees as the critical problem the schizophrenic's silent loss of inner objects or internal object connections (26–28). Reference is being made here to a developmental failure among preschizophrenic children to internalize their mothers as a stable part of themselves that remains intact during separations. There results a persistent vulnerability to experience the loss of significant others as a loss of self. Clinically, this can be seen as ego disorganization and as the

schizophrenic's inability to clearly differentiate his own identity from the identity of others. Adherents to this theory stress the importance of the therapist's stable presence in correcting this problem.

Both of these persuasions allow for the possibility that the schizophrenic's observed problem may stem from an early unremedial and probably constitutional dysfunction (the deficit hypotheses) or from an environmentally induced response pattern (the defense hypotheses). It is possible, for example, that a metabolic abnormality could make a certain affective experience qualitatively different or that an inability to internalize could result from some type of constitutional learning or perceptual handicap (21, 29–31).

Conversely, according to defense hypotheses, these same phenomena are described as active ego-initiated maneuvers to avoid the unrealistic significance assigned to the affect (e.g., being angry equals killing, being sad equals dying) or to the internalization (e.g., the loss of self or the release of previously split-off aggression against the internal object). While the Kleinians are perhaps most outspoken in their view of schizophrenia as "defense," some more traditional analytic theorists (32–34) have also supported this position. An elaboration of this argument is beyond the scope of this paper.

CONCLUSIONS

Although differences have been highlighted in this paper, the conclusion seems justified, nonetheless, that there has been some narrowing of the theory and practice of psychotherapy for schizophrenia. There is less polarization of opinion about the necessity and value of regression and prolonged hospitalization, with some recognition of the shortcomings of any generalization. There is also some narrowing of the therapist's technique away from direct id interpretations and from the actual feeding of patients. In keeping with this there seems to be a trend toward acknowledging the need for a real therapeutic relationship along with the recognition that this by itself is insufficient without analysis of the aspects of transference. There is a general impression here of a more sober businesslike approach to psychotherapy with schizophrenics and of less romanticizing than when the field was still new. This is evident in the current lessening interest in pathology and increasing interest in practical issues regarding adaptation. There is less emphasis on the schizophrenic as a victim of deprivation and more interest in his role as a perpetuator of his difficulties.

Although this narrowing gives some promise of eventually attaining more unanimity in the treatment approach among psychotherapists who treat schizophrenics, the progress seems distressingly slow. These findings indicate a need for those who practice intensive psychotherapy with schizophrenics to communicate more openly, to experiment more with other techniques, and to learn from each other's experience.

In any event there are still major differences among these experienced therapists on the variables described here. Even when therapists share a common theory, their practice may differ greatly; by the same token, when therapists practice in markedly divergent ways, they may find that they share common goals and focus. While one can filter out different schools of thought and practice, it is a mistake to expect that there will be a natural continuity between the two. What one finds is that each therapist-theoretician has a unique and often surprising admixture of the parameters of therapy described here.

An implication of this observed heterogeneity is that research efforts made in the psychotherapy of schizophrenia are better directed toward measuring the effect on outcome that specific variables in the psychotherapeutic interaction have than toward comparing psychotherapy with other treatment modalities. This necessarily means that correlational studies of process variables are needed, rather than comparative outcome studies. Methods must be worked out for quantitatively assessing the presence or absence of the various variables in the interaction. This same conclusion has been reached in reviews of past comparative research efforts (2, 35, 36). It would also be of value to assess A- and B-type therapists along such variables as passivity, focus, theory, interpretative activity, and regression. A further implication is that, when a psychotherapy is being researched, the theory and methodology of treatment must be explicitly spelled out.

Clearly, a second area in which these divergent opinions have relevance is in training psychotherapists to do intensive work with schizophrenics. There is room at this stage in the developing science for a new therapist to experiment with different techniques, to allow his own personality to exert its influence, and to develop his own ideas of what in the interaction seems to affect outcome.

SUMMARY

Major controversies continue to characterize the psychotherapy of schizophrenia. Marked differences exist among therapists with respect to where to focus the content of early interviews—on the patient's past, his interaction with the therapist, his aggression or sadness, or his realities or fantasies. A major controversy about technique concerns the role of regression in treatment—how much to permit and when to attempt to prevent it. Finally, there is disagreement as to whether to conceptualize the schizophrenic's basic failure to manage the threatened loss of a sustaining object in terms of intolerable affect or unstable introjects and, in either case, whether this basic dysfunction is a deficit or defense.

There is a need for less provincialism and for more controlled studies on process variables. Much room remains for researchers and clinicians to benefit from each other's experiences. This will be needed if in the future psychotherapy of schizophrenia is to be influenced more by research results than it has been thus far. Psychotherapists must subject their practices to the tests of research if psychotherapy is to shift from an art form into a science.

A Therapeutic Aftercare Setting for "Refractory" Chronic Schizophrenic Patients

BY PATRICK T. DONLON, M.D., RICHARD T. RADA, M.D., AND SARA W. KNIGHT, R.N.

Twenty-four chronic "refractory" schizophrenic patients were removed from a large aftercare clinic and randomly placed into one of two smaller clinics meeting biweekly. Both groups had the same therapist and both clinical settings attempted to provide nurturance and alleviate countertherapeutic interpersonal anxieties. The group that received nurturance in the setting of a social group (rather than individual supportive psychotherapy) responded much more favorably, as measured by cost efficiency, clinic attendance, and increased socialization.

IN THE PAST TWO DECADES there has been a marked shift in the treatment of the chronic schizophrenic patient from the inpatient setting to community mental health centers. Although the pathogenesis of the schizophrenias remains an enigma (1), neuroleptic agents have been found to play a significant role in psychic reintegration and rehabilitation of the schizophrenic patient. Frequently, however, the therapeutic role of the treatment setting is underestimated. The patient may be considered "refractory" or "poorly motivated" if he does not either respond clinically to his neuroleptic medication or follow the recommendations of his therapist. It might be more fitting, however, to investigate the shortcomings of the therapeutic setting, both in meeting specific emotional needs and in alleviating countertherapeutic anxieties existing within the individual patient. The purpose of this paper is to describe two treatment settings designed to examine these two specific areas with a group of chronically ill schizophrenic patients found to be "refractory" in a large aftercare clinic.

Twenty-four "treatment refractory" patients were removed from the large aftercare clinic and randomly placed into one of two biweekly clinics; they continued to receive fluphenazine enanthate. One group (Group A) focused on treating the patients in a socially oriented group setting; the other (Group B) focused on an individual supportive psychotherapeutic setting. The patients' responses to these two settings were compared by clinic attendance, degrees of increased socialization, and cost-efficiency.

Drs. Donlon and Rada are Staff Psychiatrists, Sacramento County Mental Health Services, Sacramento, Calif., and Assistant Clinical Professors, Department of Psychiatry, School of Medicine, University of California, Davis, Calif. 95616. Ms. Knight, formerly Staff Nurse at the Sacramento Medical Center, is currently a student at Arizona State University, Tempe, Ariz.

SUBJECTS

In July 1970, an aftercare clinic was established at the Sacramento County Mental Health Services to care for the large ambulatory psychotic population seen in one of its catchment areas. Clinic meetings were held twice a week, with approximately 25 to 30 of the clinic's 250 schizophrenic patients scheduled to attend a given session. The clinics emphasized multidisciplinary primary therapists, social interaction between staff and patients, an institutional alliance, refreshments, periodic entertainment, and an adaptive psychotherapeutic approach (2, 3).

Twenty-four patients were considered "treatment refractory" in the large clinic meetings. They were heterogeneous in age, race, socioeconomic class, duration of psychiatric symptoms, medication requirements, and total duration of psychiatric hospitalizations. All, however, had in common a marked anxiety in interpersonal relationships and a tendency to be aloof, suspicious, and noncommunicative. Positive rapport between the therapist or institution and the patients was absent in every case. The diagnosis of chronic schizophrenia or chronic paranoid schizophrenia was well documented for all patients on the basis of both the diagnostic criteria of Bleuler (4) and maladaptive life-styles.

Of the 24 patients, 11 were women and 13 were men. Their ages ranged from 19 to 51 years, with an average of 33. Seventeen patients were white, four Chicano, two black, and one Oriental. None was financially self-supporting and all were in socioeconomic classes IV and V (5). The total duration of psychiatric hospitalizations per patient varied from two months to 18 years, with a mean of 3.2 years.

All of these patients were considered difficult management cases. In the 18-week comparison period preceding their transfer to the new settings, seven patients required hospitalization for psychotic decompensation; three other patients made suidical gestures but did not require hospitalization. Furthermore, there were 48 unkept scheduled appointments, as well as 33 visits to the Psychiatric Crisis Clinic. All patients were placed on fluphenazine enanthate (a long-acting injectable neuroleptic) to better ensure their receiving medication. None was consistently maintained on a therapeutic dosage of depot medication, however, because all remained irregular in keeping their clinic appointments.

METHOD

It was hoped that these 24 aloof and suspicious "re-

fractory" patients would respond more favorably if placed under the care of a single therapist and in a therapeutic setting that would be more suitable for meeting their emotional needs and alleviating their marked countertherapeutic interpersonal anxieties. Two new clinics were established. One featured socialization and refreshments within a group setting, while the other offered closeness with the therapist through individual supportive psychotherapy but permitted emotional distance from fellow patients. The patients were matched as closely as possible for age, sex, duration of illness, severity of symptoms, and medication requirements and were then randomly placed into either Group A or Group B. The 18-week evaluation period consisted of nine biweekly clinic visits, each lasting one and a half hours. The groups met on alternate weeks. The primary therapist (S.W.K.), a psychiatric nurse, met with all 24 patients in consultation with a psychiatrist (P.T.D.).

Group A patients were warmly greeted in the therapy room by the primary therapist as they arrived at the Mental Health Clinic. They were immediately offered refreshments (punch, coffee, and cookies). The chairs were arranged in a circle. No attempt was made to use uncovering psychotherapy during the 30-minute group meeting, which the therapist both structured and led. The goals of the clinic were to allay a patient's debilitating interpersonal anxiety with a nonthreatening milieu of acceptance and emotional support and to provide nurturance through warmth and refreshments—all administered within a group setting. At the conclusion of the 30-minute group meeting, each patient was seen individually for approximately five minutes and given his injection, necessary prescriptions, and a return appointment slip. Patients were told to contact the therapist in the interim if necessary.

The room and chair arrangement were the same for the Group B patients, but refreshments were not available and the therapist did not either initiate group interaction or promote interpersonal contact between the patients. The patients were seen individually by the therapist, although they waited as a group in the clinic room prior to being seen. The goals for Group B patients were to provide a nonthreatening, accepting, supportive therapeutic relationship with freedom from the stress of group membership and to provide nurturance in the form of ten to 20 minutes of individual therapy.

RESULTS

Three patients from Group A and two from Group B dropped out, and the study was continued with 19 patients. During the study period, Crisis Clinic visits were reduced to four for both groups and no hospitalizations were required. Furthermore, there was no record that any patient received psychiatric care from other private or public mental health agencies. The patients' responses to the two treatment settings are summarized below.

Attendance

There were seven late arrivals for Group A and 18 for Group B (late arrivals were those who arrived one hour after the scheduled appointment time). There were five unkept appointments for Group A, compared with 31 for Group B. During the 18-week prestudy period, there had been 21 unkept appointments for Group A and 27 for Group B.

In general, the Group A patients tended to arrive on time throughout the study, in contrast to an increasingly erratic attendance record for Group B patients. For the last six sessions, an average of eight Group A patients and three Group B patients arrived on time for their appointments.

Socialization

Very little social interaction occurred in either group during the first two sessions. By the third session, Group A patients began engaging in conversation upon entering the room and became more spontaneous in group interaction. Five of the patients consistently began bringing friends or relatives to the meetings. In addition, by the sixth session they were able to socialize without the encouragement of the therapist and requested that the group meeting be extended from 30 to 45 minutes. On the other hand, the social interaction of Group B patients remained distant, isolated, and nonspontaneous.

Cost Efficiency for Therapist's Hours

The cost efficiency for each group was established by comparing the time required for therapy (including the extension of clinic time for late visits and the rescheduling of appointments), writing letters to patients who did not accept telephone calls, and telephone calls to and from patients. In each of these areas Group B patients required more time than Group A patients.

When budgeting only for the therapist's total hours (at a salary of $4.97 per hour), the total cost of therapy for Group A patients was $216.20, compared to $352.47 for Group B (there were 27.42 hours of additional therapy time for Group B, which cost $136.27). Subtracting the cost of the refreshments ($18.00), there is a cost differential of $118.27 for the two treatment settings. During this study period, there were 87 visits for Group A and 92 for Group B. Using the above figures, the average Group A visit lasted 30 minutes and cost $2.49 for therapy time. The average was 46.2 minutes per visit for Group B patients, at a cost of $3.83 per visit.

DISCUSSION

As Silverstein noted, a high readmission rate for psychiatric outpatients frequently reflects a failure in the delivery of aftercare services (6). Enthusiastic and innovative programs appear to be imperative if the readmission rate is to be kept at low levels and if successful outpatient management and rehabilitation of the mentally ill is to be maintained. To provide services efficiently and economically, any aftercare setting must attempt to adapt itself by careful planning to best meet the individual needs and anxieties of its patients.

In this study, Group A patients received assistance n mastering their interpersonal anxieties by being rewarded for attendance with refreshments and through the facilitory role of the therapist in a relatively nonthreatening social setting. Apparently, the patients had to learn that socialization could be a rewarding rather than a frightening experience before they could be successfully managed as outpatients. The alleviation of countertherapeutic interpersonal anxiety and the offering of nurturance (emotional support and refreshments) within a social setting was instrumental in establishing a therapeutic milieu for the formerly "refractory" Group A patients.

Krebs concluded that attendance can be used to measure the outcome of a community mental health program, the therapeutic relationship, and patient motivation (7). Certainly, the disparity between the attendance records of the two groups reflects the lack of rapport with Group B patients, who continued to miss appointments in spite of repeated telephone contacts by the therapists. Attendance for Group B patients was an anxiety-provoking experience that increased their rate of failure to keep appointments.

Socially, there was a marked change in Group A patients over time, compared with Group B. Group A patients not only continued to arrive on time, but also encouraged friends or relatives to join them. Interaction soon became spontaneous, and socialization was considered a rewarding rather than an anxiety-provoking experience. Conversely, Group B patients did not master their interpersonal anxieties and tended to avoid the clinical setting. The therapeutic role of the group setting (8) and the acceptance and gratification of the patient's oral dependency needs through emotional support and refreshments (9) have been reported previously by other investigators.

May addressed himself to the cost efficiency of five treatment modalities for hospitalized schizophrenics and concluded that the most effective program may also be among the most economical (10). No doubt, effective and economically efficient treatment is also extremely important in the outpatient management of the schizophrenic patient, since the caseloads in many facilities are frequently large. In this study, the saving of 27.42 therapeutic hours for Group A patients was appreciable and the quality of care was also maintained or increased, as measured by patient response. In addition, aggressive use of the telephone helped to reduce expensive readmission to the inpatient unit and also reduced the use of the Crisis Clinic.

The role of the therapist (S.W.K.) along with her professional bias and attitudes were undoubtedly important factors affecting the clinical responses of the patients in the two groups. Although the therapist was the same for both groups and initially felt equally at ease (or anxious) in both groups, she began to realize, after approximately two months, that she preferred working with the Group A patients. The extent to which a happy, comfortable therapist promoted better emotional health and socialization in Group A or the extent to which a responding, improving patient group reinforced the therapist's positive attitude is impossible to assess in this study. Undoubtedly both factors were operating.

Finally, outpatient studies comparing treatment settings and modalities of treatment are difficult to establish methodologically. Few well-controlled studies have been reported. Increasing emphasis on the outpatient management of the mentally ill, including cost efficiency and utilization review, points to the need for further investigation in this area.

Relapsed Schizophrenics: Earlier Discharge from the Hospital After Cereal-Free, Milk-Free Diet

BY F.C. DOHAN, M.D., AND J.C. GRASBERGER, M.D.

Routinely treated schizophrenics, who on admission were randomly assigned to a diet free of cereal grains and milk while on the locked ward, were discharged from the hospital about twice as rapidly as control patients assigned to a high-cereal diet. Wheat gluten secretly added to the cereal-free diet abolished this effect. These and previous findings suggest that cereal grains may be pathogenic for those hereditarily predisposed to schizophrenia just as they are for celiac disease, a disorder that may be genetically related.

WE HAVE PREVIOUSLY REPORTED that a cereal-free, milk-free diet hastened the improvement of relapsed schizophrenics ($p<.01$) as judged by the duration of their stay on a locked ward (1, 2). This was apparently not due to psychological factors affecting staff or patients, since the effect disappeared when wheat gluten was secretly added to the diet. This suggests that diet is of therapeutic value and that cereal grains may be one of the pathogenic factors affecting those susceptible through heredity to schizophrenia. This hypothesis (3) is further supported by the following:

1. Epidemiologic data demonstrating a strong correlation ($r = 0.96$, $p<.01$) between first admissions for schizophrenia and the consumption of wheat plus rye (2, 3).

2. Observations indicating that celiac disease (gluten enteropathy), which is probably based on polygenic inheritance (4) and is ameliorated by not eating wheat gluten and its analogues in other cereal grains, and schizophrenia, which is probably also polygenic (5), occur in the same individual more frequently than would be expected by chance (2, 6).

3. Data from sizable samples of schizophrenics in the pre-phenothiazine era provided findings similar to those in celiac patients, including gastrointestinal and other symptoms (7–10), metabolic changes (9, 11), failure to gain weight on high-calorie diets (11, 12), and histologic changes in the intestines and mesenteric lymph nodes (10, 13, 14).

4. Reports of frequent psychiatric disturbances in celiac patients, including one instance of hallucination (15, 16), which may rapidly be made manifest by gluten administration (6), show improvement soon after the removal of gluten from the diet (16–18), and in some cases are similar to disturbances seen in schizophrenia (6, 15).

The purpose of our present study was to examine the effect of a cereal grain-free, milk-free diet upon relapsed schizophrenics as measured by another and more commonly used index of improvement than the length of stay on the locked ward, which was the index used in our previous study (1, 2). We now report data that have become available since that time—the length of stay until discharge from the hospital of relapsed schizophrenics who were on the test diets during their stay on the locked ward. We included only those patients readmitted or admitted for the first time to the Coatesville, Pa., Veterans Administration Hospital during our previous study periods (I and II) and during an additional admission period (IIIa). Our previous study included patients transferred to the locked ward from the open wards as well as those assigned to the locked ward on admission to the hospital.

METHOD

All subjects were male veterans. The means and distributions of their ages by experimental groups did not differ significantly. The mean for all subjects was 38 years. The diagnostic criteria were those outlined in the 1952 edition of the American Psychiatric Association's *Diagnostic and Statistical Manual.* Aside from the diet while on the locked ward, all patients were treated routinely during their period on the locked ward and after their release to the open wards. Chlorpromazine and thioridazine were the most frequently administered antischizophrenic medications. After review of their cases at a staff conference, patients who were improved sufficiently or considered likely to experience no further benefit from hospitalization were discharged.

We report here the length of time from admission to discharge from the hospital (within approximately one year after the end of each admission period) for those schizophrenics who entered the locked study ward on the day of their admission to the Coatesville Veterans Administration Hospital as new admissions or as read-

missions to it. Only those who remained on the locked ward longer than one day are included in the analysis.

During the three admission periods, all patients who entered the locked ward from either outside or inside the hospital were immediately randomly assigned (initially by odd or even Social Security numbers and later by random numbers in balanced groups of four) to various experimental diets. The experimental diets were provided only during the patients' stay on the locked ward. After release from the locked ward to an open ward (which usually occurred by the 15th day), all patients were subjected to the same diet, i.e., the usual hospital diet. This diet afforded ample opportunity to consume large amounts of cereal grain products and milk.

During period I (175 days) and period IIIa (148 days) patients were randomly assigned either to a diet free of all cereal grain and milk products (CFMF diet) or to the usual milk-containing hospital diet, which was made somewhat higher in cereal grains (e.g., spaghetti instead of potatoes)—the high-cereal diet (HC diet). Milk was omitted from the CFMF diet because it produces a relapse in some celiac patients and thus, we hypothesized, may be harmful to some schizophrenics. During admission period II (143 days) patients were randomly assigned to either the HC diet or to the CFMF diet to which wheat gluten (about 19 gm./day) had been secretly added. This is approximately the amount consumed in breads, cakes, and so forth by the subjects on the HC diet. Strict mealtime and between-meal diet discipline was attempted for all patients during their stay on the locked ward throughout the entire study.

At the end of each admission period the patients were continued on the locked ward diets for a week to ten days, thus providing a "corridor" before the beginning of a new period. Patients admitted during the corridor period were not included in the experiment. Only 11 of the patients in this study were not released from the locked ward to an open ward before the beginning of a new period. All of them had been on either the HC or CFMF plus gluten diet. This is in accord with our previous observation that a CFMF diet is associated with an earlier release from the locked ward. Patients transferred to the medical or surgical wards or to another hospital were not included in this study.

Those schizophrenics who were admitted to the hospital as new admissions or readmissions during each of the admission periods and who were assigned to a particular experimental diet can be considered one cohort. Since we hypothesized that the CFMF diet would be associated with earlier discharge from the hospital and this diet was given during periods I and IIIa, the results from the two cohorts that were assigned to the CFMF diet in these two periods were combined for analysis, as were the results from the two HC cohorts.

RESULTS

Table 1 demonstrates that the proportion of relapsed schizophrenics in the CFMF diet group who were discharged from the hospital during the first six months was considerably and significantly greater than that in the HC group. In contrast, table 2 shows that when gluten was secretly added to the CFMF diet this difference did not occur.

CFMF Diet Versus HC Diet

The significance of the differences in the cumulative proportions of the 59 CFMF schizophrenics and the 56 HC schizophrenics discharged from the hospital at successive ten-day intervals after admission was analyzed by Fisher's exact method. Table 1 shows the results at 30-day intervals. The cumulative percentage discharged of the CFMF group at the end of each ten-day interval from day 40 through day 190 was significantly greater than that of the HC group. The probability that the differences between the two groups was due to chance alone was less than three percent in 13 of the 16 comparisons. On days 90, 150, and 160 the probability was less than one percent. Thus, it seems unlikely that the more rapid discharge of the CFMF group was due to chance alone.

The increased rate of discharge occurred during the

TABLE 2

The Effect on Discharge from the Hospital of Adding Wheat Gluten to the Diet Free of All Cereal Grains and Milk (CFMF) Compared with High-Cereal Diet (HC)

*Fisher's exact method.

first 90 days after admission. The cumulative proportion discharged at the end of 90 days after admission was 37.2 percent for the CFMF group, compared with 16.1 percent for the HC group. Furthermore, of the number in each diet group who were in the hospital on days 0, 30, and 60, the proportion discharged in the following 30 days was 10.2, 20.8, and 11.9 percent for the CFMF group and 3.6, 9.3, and 4.1 percent for the HC group; that is, the absolute discharge rate of the CFMF group for each of the three 30-day intervals was more than twice that of the HC group. However, after that time the percentage of the remainder discharged was about the same for both groups.

Considering only those patients discharged from the hospital, the median day of discharge for both groups combined was day 65; the median day (interpolated) was day 102 for the HC group and day 53 for the CFMF group. The average time until discharge for the discharged CFMF patients (77 days) was 55 percent of that of the discharged HC patients (139 days).

Only one patient was admitted to the hospital twice, each time on a different diet. When randomly assigned to the HC diet he remained on the locked ward for 17 days and left the hospital without permission (AWOL) on day 65. When he was readmitted 11 months later and randomly assigned to the CFMF diet he stayed seven days on the locked ward and was discharged on day 22.

Of the 22 HC patients who were later discharged, 10 were returned to the locked ward one to six times because of their behavior on the open ward. Of these, three were then randomly assigned to the CFMF diet. They were discharged 21, 78, and 87 days later, all in less than the median time to discharge (102 days) for the HC group. Of the 30 discharged schizophrenics in the CFMF group, only three reentered the locked ward (one or two times), all on the CFMF diet.

CFMF Plus Gluten Diet Versus HC Diet

Analysis by Fisher's exact method at ten-day intervals of the cumulative proportions discharged from the CFMF plus gluten group versus the HC group showed that the lowest probability that the differences were due to chance alone was 28.4 percent and that all other values except one were greater than 40 percent. Thus, as is shown in table 2, there was no significant difference in the rate of discharge between the HC group and the CFMF group when gluten was secretly added to the CFMF diet.

DISCUSSION

During the first 90 days after admission to the hospital, those schizophrenics assigned to the CFMF diet were discharged more than twice as fast as those in the HC control group. After that period the rates became similar. We suggest this might be because the subjects were on the CFMF diet only during the time they were on the locked ward (prior to their release to an open ward), which for 76 percent of the entire CFMF group was no more than 15 days. Thus, any therapeutic effect of this brief period on the CFMF diet may have lasted for only a few months after resumption of the normal hospital diet. It is also possible that only a proportion of those diagnosed as schizophrenic respond to a CFMF diet.

We have previously observed (1, 2) that the effect of the CFMF diet on improvement of relapsed schizophrenics was most prominent within the first week or two. The effect on the discharge rate occurred in the first three months. Perhaps a longer period on the CFMF diet would have extended this effect. The psychological symptoms of celiac (gluten enteropathy) patients also usually improve considerably within a week or two, often within a few days (16–18), when they are placed on a "gluten-free" diet (i.e., omitting foods made from wheat, rye, barley, and sometimes oats). The symptoms often but not always recur in weeks to years after resuming the usual gluten-containing diet. However, we are unaware of reports of sustained improvement of celiac patients after a period as short as the two to ten days of this diet experienced by 24 (80 percent) of the 30 discharged CFMF schizophrenics.

Many observers state that celiac patients, after being

on a gluten-free diet, find they can eat gluten-containing food for weeks to years with no (or only minor) subjective symptoms prior to clinical relapse. Unfortunately, the length of time from starting a gluten-free diet to the development of tolerance to gluten and its analogues has not been well studied. Cooke and his co-workers (19) in a report on 50 celiac patients noted that 25 of them were eating foods containing gluten, seven of them without any treatment whatsoever after the initial treatment period. They noted, as have others, that after the initial treatment, apart from the intestinal biopsy findings of mucosal atrophy, there was surprisingly little difference between celiac patients who were on a gluten-free diet and those who were not. It is customary, nevertheless, to recommend that the gluten-free diet be maintained for many years. The clinical reports that "psychic stress" often precedes relapse and the careful observation of Grant that relapses in celiac patients tolerating gluten occurred when the life situation was such that the patient "gave up" (20) are of considerable interest in view of the probable role of psychic factors in the relapse of schizophrenics.

In contrast to the beneficial effects of the CFMF diet, the relapsed schizophrenics on the CFMF diet to which wheat gluten was added (without the knowledge of staff or patients) were not discharged from the hospital significantly faster than their temporal controls on the HC diet. This finding suggests that the effect of the CFMF diet on the discharge rate was not due to any bias of the patients or staff. During this period there was also no difference in the rate of release from the locked ward of the HC and CFMF plus gluten groups composed of schizophrenics entering the locked ward from open wards or as new admissions to the hospital (1, 2).

These adverse effects on relapsed schizophrenics of gluten added to the CFMF diet indicate that, as in celiac disease, "toxicity" is associated with the gluten fraction of wheat. However, epidemiologic data indicate that schizophrenia occurs, although possibly with lesser frequency, in societies that eat no wheat or rye but do eat other cereal grains (3) such as maize and millets, which contain gluten-like proteins but with a lesser proportion of glutamic acid, glutamine, and proline.

CONCLUSIONS

We believe that the beneficial effect of the cereal grain-free, milk-free diet on discharge rates adds strong support to the hypothesis that cereal grains may be involved in the pathogenesis of schizophrenia (1–3, 6, 15) as well as in celiac disease. We therefore suggest that the effects of this diet on acute new or recently relapsed schizophrenics deserve careful testing by other investigators. If the effect of diet on persistently chronic schizophrenics is to be tested we suggest the diet be continued for at least six months to a year. The examination of unmedicated active schizophrenics, who have been on a high gluten-containing diet for weeks or months, by the same techniques used in studying celiac disease (in particular, peroral intestinal biopsy) should be fruitful, as should an investigation of the possibility that one or more genes may be common to the two diseases.

The annual direct plus indirect cost of schizophrenia in the United States for the two to three million Americans carrying this diagnosis was recently estimated as approximately 14 billion dollars (21). If diet proves to be an effective long-term therapeutic adjunct, as our preliminary short-term experiments and epidemiologic observations lead us to postulate, the tremendous human burden and financial costs of this relatively common disorder should be substantially decreased.

Mesoridazine Versus Chlorpromazine in Acute Schizophrenia: A Double-Blind Investigation

BY T.A. HAMID, M.D., AND WILLIAM J. WERTZ, M.D.

A double-blind comparison of mesoridazine and chlorpromazine with 91 newly admitted, acutely psychotic patients showed that symptoms grouped in the following composites improved significantly more in the mesoridazine patients than in the chlorpromazine patients: motor activity, attitude and behavior, emotional response, and ideation and thought processes. The mesoridazine patients experienced less sedation than the chlorpromazine patients.

EMOTIONALLY DISTURBED PATIENTS admitted to a hospital emergency room are frequently delusional, combative, assaultive, agitated, hostile, hallucinating, incoherent, and generally uncontrollable. In many hospitals, particularly overcrowded urban ones, emergency room psychiatric procedures are intended merely to bring the patient's gross symptoms under control. While awaiting either release from the hospital or transfer to a psychiatric ward, the institution of psychotherapeutic measures may be delayed, often by several days.

Many psychiatric treatment centers and hospitals are assessing the situation from within. One group, as reported by Rhine and Mayerson (1), has implemented a coordinated crisis program for both inpatients and outpatients. Under this program, experienced psychiatrists and other specialized personnel have replaced resident doctors in the psychiatric emergency rooms. Admission to an emergency room and subsequent treatment is considered the start of therapy rather than an end in itself.

With a shift in emphasis from mere patient "disposition" or "parking" to early therapeutic programs, modifications in drug requirements should be considered. Traditionally, a patient in an emergency ward who presents severe psychotic symptoms is given parenteral injections of one of the phenothiazines. Patients generally become heavily sedated, which is not conducive to the early implementation of combined treatment consisting of chemotherapy, psychotherapy, and supportive therapy. It would be preferable to find an agent that can rapidly control acute psychotic manifestations yet render the patient receptive to early therapy.

The authors were both formerly with Emergency Psychiatric Services, Detroit General Hospital, where Dr. Hamid was Resident Psychiatrist and Dr. Wertz was Director. Dr. Hamid is now at 16 Nile St., Giza, Egypt, U.A.R. Dr. Wertz is now Superintendent, Detroit Psychiatric Institute, 1151 Taylor St., Detroit, Mich. 48202. Address reprint requests to Dr. Wertz.

The present study compared two chemically different phenothiazine derivatives, mesoridazine (a piperidine) and chlorpromazine (an aliphatic). The purpose of the study was to determine the efficacy and safety of the compounds in controlling psychotic symptoms during a 24-hour period. Emphasis was placed on determining the type of symptoms that would respond and the degree of sedation that would occur with each treatment during the 24-hour period.

METHOD

Patients selected for the study presented a clinical picture consistent with schizophrenia. After the patients had received a medical and psychiatric examination and their related histories were obtained, they were considered for inclusion in the study if they exhibited acute psychotic symptoms sufficiently severe to warrant the parenteral administration of a neuroleptic. Patients exhibiting mental deficiency, acute or chronic alcoholism, drug addiction, epilepsy, or organic brain syndrome were automatically excluded. Pregnancy, severe central nervous system depression, and a hypersensitivity to phenothiazines also constituted reasons for exclusion. Patients who had received a neuroleptic or antidepressant during the two weeks prior to admission were excluded from the study, as were patients who had received a minor tranquilizer within three days of the study.

Ninety-one patients who participated in the study were assigned medication according to a randomized design that provided two treatment groups. One group of 47 patients consisted of 21 women and 26 men whose mean age was 36.1 years (range: 16–71 years) and who had previous hospitalizations averaging 16.4 months (range: 0–132 months). This group was treated with mesoridazine. The other group of 44 patients consisted of 20 women and 24 men whose mean age was 34.5 years (range: 18–65 years) and who had previous hospitalizations averaging 19.1 months (range: 0–192 months). This group was treated with chlorpromazine. A chi-square analysis performed at the conclusion of the study confirmed that the groups were homogeneous with respect to sex, height, weight, and diagnosis.

It was not possible to prepare identical ampules of mesoridazine and chlorpromazine. Therefore, to preserve the double-blind aspect of the study, the functions of drug administration and patient evaluation were completely separate. The physician conducted the assessments and

specified all dosage adjustments. The drugs were administered by a registered nurse. The double-blind aspect was well preserved, in that at no time was the physician aware of what drug was administered.

Each patient received an initial injection of 1 cc. (25 mg./cc.) of either drug by deep intramuscular injection, according to the manufacturer's recommendation. Patients received an additional 1 cc. of their assigned treatment drug one hour later. Following the administration of the second 1 cc. of each drug, patients were evaluated for the degree of sedation, in order to assess the sedation effects of equal amounts of the two drugs. Thereafter, the physician could prescribe additional injections every four hours when necessary, up to a 24-hour maximum of 400 mg. of chlorpromazine or 200 mg. of mesoridazine. After the first two doses, the physician ordered dosages of medication as though he were prescribing only chlorpromazine. The nurse carried out the instructions for patients taking mesoridazine with the aid of an equivalency chart that listed dosages in a 2:1 ratio of chlorpromazine to mesoridazine.

No other tranquilizers, neuroleptics, or antidepressants were permitted during the study. Antiparkinsonian drugs were not employed. Further, antihypertensive agents such as reserpine or pargyline were prohibited because of their psychoactivity. Supportive medications considered necessary for the patient's welfare were permitted; these were described in the case record.

The patients' progress was assessed during the study with the aid of three formal rating scales. Symptomatic changes were measured using a Specified Symptom Rating Scale (2). This assessment consists of nine major symptom composites with the headings: Motor Activity, Attitude and Behavior, Emotional Response, Ideation and Thought Processes, Perception, Sensorium, Orientation, Memory, and Somatic Manifestations. A total of 78 symptoms was included in these composites, and each was rated prior to treatment and again after two and 24 hours. Scoring was based on a scale from 1 to 4, in which higher scores corresponded to greater symptom severity. Each patient's composite score was determined by summing the scores for each of the individual items comprising the composite and then dividing that by the number of "target symptom" items in the composite for that patient.

A rating was also conducted at two and at 24 hours to observe the extent to which the degree of sedation contributed to the drugs' therapeutic effects. The physician made this rating by judging to what degree the action of the drug was manifested by sedation. An effort was also made to distinguish sedation from excessive drowsiness, which was rated in the symptom composite of Sensorium and which included the components of clouding, degree of drowsiness, and stupor. Drowsiness was considered excessive if it interfered with hospital procedures or the patient's participation in treatment.

Global improvement was evaluated for each patient at the conclusion of the 24-hour observation period. The incidence and severity of any adverse effects were also recorded at this time.

Change scores were obtained for each symptom and for each composite of the Specified Symptom Rating Scale by subtracting the differences between the baseline value and the two- and 24-hour assessments. The Student t test was used to determine whether the mean change score at each of the specified observation periods was significantly different from baseline. In order to eliminate differences in pretreatment scores as a possible confounding factor in making the drug comparison, an analysis of covariance (3) analogue to Student's t test was used. If the assumptions requisite to this procedure were not met, a simple Student's t test was run to compare the mean change scores for the two agents. Various contingency table analyses were undertaken to test relative differences in global evaluation and the relationships between sedation and drowsiness.

RESULTS

Mesoridazine and chlorpromazine were employed in a range of dosages for the 24-hour study period. Numerous patients in each group received the maximum permissible dosage. The mean 24-hour dose of mesoridazine was 148 mg. (range: 88–200 mg.) and that of chlorpromazine was 215 mg. (range: 50–400 mg.).

The comparison of the treatment effects on the symptom composites after two and 24 hours appears in table 1. After two hours, at the recommended dosages, mesoridazine provided slightly more control of symptoms than did chlorpromazine. After 24 hours, by contrast, mesoridazine was significantly favored ($p < .01$) over chlorpromazine in reducing the severity of the symptoms measured in the following composites: Motor Activity, Attitude and Behavior, Emotional Response, and Ideation and Thought Processes. These composites consisted of the symptoms that occurred with the greatest frequency and severity before treatment. The average pretreatment scores for symptoms in these composites were similar for both treatment groups, in that they ranged from 2.8 to 3.3, scores that represent moderate severity. In the mesoridazine group, average symptom severity was reduced from moderately severe to mild, while many symptoms in the chlorpromazine group remained moderately severe, particularly those included in the Emotional Response category.

Individual symptoms within the composites were analyzed by the t test and analysis of covariance when there were at least 16 patients manifesting the symptom before treatment. After two hours the majority of symptoms were significantly reduced from the baseline, but there were no differences between the relative effects of mesoridazine and chlorpromazine. However, as is consistent with the results for the composites, mesoridazine provided significantly greater symptom remission than chlorpromazine at 24 hours. Two symptom clusters were particularly responsive to mesoridazine. Within the composite for Attitude and Behavior, aggressiveness, assertiveness, resistiveness, and unpredictability were reduced by an average of two rating levels, from severe to mild. In

TABLE 1
Comparison of Treatment Effects of Mesoridazine and Chlorpromazine

††$p < .05$.

the composite for Ideation and Thought Processes, mesoridazine demonstrated a marked control of autism, ambivalence of thought, irrelevance, and looseness. Mesoridazine was also superior to chlorpromazine in controlling impulsiveness (Motor Activity) and hostility and inappropriateness (Emotional Response). There were no symptoms for which chlorpromazine was more effective than mesoridazine.

While the above analyses dealt exclusively with average scores, another dimension of the relative drug effects was reflected in the number of patients rendered symptom-free by either treatment. Agitation, impulsiveness, assertiveness, combativeness, unpredictability, ambivalence of thought, and irrelevance were all completely remitted, as rated, in significantly more of the patients treated with mesoridazine. Mesoridazine also controlled symptoms of hyperactivity, verbosity, aggressiveness, assaultiveness, resistiveness, inappropriateness, suspiciousness, and hallucinations in a considerable number of patients.

The physician's impressions, as expressed in the global ratings, corroborated the findings of symptomatic improvement. Measured on a four-point scale ranging from 1 = very much improved to 4 = worse, 42 percent of the mesoridazine patients were very much improved; only ten percent of the chlorpromazine patients were considered very much improved. Fifty-one percent of the mesoridazine patients and 64 percent of the chlorpromazine patients were improved. The remaining patients showed no change; none worsened.

The ratings for Sensorium revealed that after two hours both treatment groups were significantly more drowsy than they had been before treatment. However, patients treated with mesoridazine had significantly less drowsiness than those treated with chlorpromazine. After 24 hours, patients in both treatment groups were less drowsy than they had been at two hours. Although patients treated with mesoridazine were somewhat less drowsy than those treated with chlorpromazine at the end of 24 hours, the difference between the two groups was not significant.

Ratings made for sedation revealed that the effects of mesoridazine were less frequently accompanied by sedation than were those of chlorpromazine. Consistently fewer patients treated with mesoridazine were sedated after two and 24 hours.

Only three side effects were observed during the study. One 23-year-old woman suffered a generalized epileptic seizure after 50 mg. of mesoridazine. Following an identical dose of chlorpromazine, a 48-year-old woman exhibited involuntary movements and a 49-year-old man suffered shock and prostration.

DISCUSSION

The effectiveness of mesoridazine as compared with chlorpromazine has been demonstrated in long-term studies of psychotic patients (4–9). In those studies, mesoridazine alleviated many of the manifestations of schizophrenia but appeared to be particularly effective in the area of thought disorders (conceptual disorganization, hallucinatory behavior, and unusual thought content). The results of the present investigation confirm the symptomatic improvement observed in long-term studies and show that the onset of mesoridazine's activity can be observed even on the first day of treatment. This rapid onset of action makes mesoridazine valuable in the treatment of psychiatric emergencies.

The effectiveness of mesoridazine administered parenterally in emergency situations has been observed by other investigators. Ast and associates (8) treated acute psychotic patients and found they improved markedly, particularly in hallucinatory behavior. Brauzer and Gold-

stein (9) likewise found that mesoridazine improved the psychological state of psychotic patients during their first 72 hours of hospitalization. These patients' conceptual disorganization responded better to mesoridazine than to chlorpromazine.

In this study, the effects of mesoridazine could be distinguished from those of chlorpromazine in several areas. By the end of 24 hours, mesoridazine had produced greater improvement than chlorpromazine in all the symptom composites of observed symptoms. The improvement was significantly greater for the composites indicative of disturbances in Motor Activity, Attitude and Behavior, Emotional Response, and Ideation and Thought Processes. Moreover, the therapeutic effect of mesoridazine in these and other composites was manifested with less sedation and less effect on the sensorium than occurred with chlorpromazine. Mesoridazine, therefore, proved to be a valuable agent for emergency psychiatric treatment because it provided excellent control of symptoms, yet allowed patients to be alert, accessible, and responsive to therapeutic and custodial procedures. Specific treatment rather than mere short-term control could begin on the first day.

CONCLUSIONS

Ninety-one newly admitted schizophrenic patients were selected to participate in a controlled double-blind comparison of mesoridazine and chlorpromazine. The drugs were compared after two and 24 hours with respect to their ability to control acute symptoms grouped in nine composites. Each drug was initially administered intramuscularly in a 25-mg. dose that was repeated in one hour. Thereafter, dosages were prescribed according to individual need, not to exceed 200 mg. of mesoridazine or 400 mg. of chlorpromazine in the 24-hour period.

Patients treated with either mesoridazine or chlorpromazine experienced relief of symptoms after two and 24 hours. However, after 24 hours, differences between treatment significantly favored patients treated with mesoridazine for the composites of Motor Activity, Attitude and Behavior, Emotional Response, and Ideation and Thought Processes. The therapeutic effects of mesoridazine were manifested with less sedation than occurred with chlorpromazine. As a result, patients who received mesoridazine were more accessible and responsive to the therapeutic, diagnostic, and custodial procedures associated with their early treatment.

EDITORIAL

The Treatment of Schizophrenia: Illusion or Elusion?

SHORTLY BEFORE THE TURN OF THE CENTURY the famed pathologist Rudolph Virchow was asked for a definition of cancer. He responded that he would not attempt such a definition even under the threat of torture. His very sensible position is equally applicable to schizophrenia. It is such a highly complex and multivariate disorder that our attempts to conceptualize it adequately have repeatedly resulted in disappointment. Inadequate conceptualization produces diagnostic unreliability. It is well known that nosologic irrelevancies such as the psychiatrist's geographic locale, theoretical preference, and general experience determine his diagnostic practices.

Despite this diagnostic disorder there are certain points of general agreement. Schizophrenia can be seen both as a process and as a clinical syndrome. From the former point of view, it is the progressive development over time of a psychotic condition from a nonpsychotic premorbid state. The latter and more common usage is as a label for a clinical syndrome that can be defined by the presence of certain specifiable signs and symptoms. In a very real sense, the schizophrenic syndrome is anything we wish it to be. The unfortunate problem is that psychiatrists in fact differ sharply in what they wish it to be. Highly personal if not autistic definitions abound. This is not because of the poor reliability of the individual diagnostic criteria, but rather because of individual differences in willingness to attach the label. The remarkable point is that a group of psychiatrists who show very high agreement on which diagnostic signs are present or absent will then differ sharply in the diagnosis they make on the basis of those signs. This paradox gives us an important insight into the problem of schizophrenia. Seriously disturbed patients evoke in the psychiatrist a variety of unpleasant feelings that influence his willingness and ability to make an accurate diagnostic statement. It is not unfair to conclude that the psychiatrist, when faced by madness, also binds his anxiety in peculiar ways.

If the psychiatrist finds schizophrenia difficult to comprehend and diagnose, we should expect him to find it more difficult to treat. This is in fact the case. Some psychiatrists limit or even exclude patients from their practices because they do not find treatment to be a personally satisfying experience. A heterogeneous category consisting of several populations, each of which is highly variable, produces a therapeutic nightmare. The result is a variety of "preferred" treatments, ranging from the biologic to the psychologic. What the treatments lack in efficacy their advocates often make up in vehemence. One can reasonably raise a question concerning the rationale for any exclusive treatment when there is so much diagnostic heterogeneity in the patient

In this section, the Editor samples varied opinions on topical problems. The opinions expressed herein are not necessarily those of the Editor, nor can they in any way be construed as marking the official policy of the Journal.

sample. It seems of doubtful validity to speak of the "treatment of choice" in a condition that varies greatly in its premorbid picture, onset, presenting signs, course, and outcome. Clearly, it is this very ambiguity which permits passionate partisan positions. There would be no room for such affective displays if we had more knowledge.

Once we recognize the problem of diagnostic heterogeneity there are several courses available. The most obvious is to reduce the heterogeneity through all available means. During the interim, we must recognize that the heterogeneity exists and therefore no single treatment modality can be the best. In a syndrome as variable as schizophrenia, we should expect virtually any specifiable intervention to be useful in some subset of the total population. The variation in the individual patient over time can also be so great that the treatment approach which is best suited at one point is less well suited at another. We can conclude that we must have a range of treatments that approximates the variability of the syndrome. There need not be a correspondence between the type of intervention and the etiology. In other words, it is not necessary to administer a biochemical intervention for the genetic contribution and a psychologic intervention for the effects of the environment. The syndrome is the end product of a genetic-environmental interaction and can be influenced to varying degrees by both chemical and social means.

The individual who wishes to treat schizophrenic patients cannot be bound by the shackles of orthodox theory. He must be flexible and willing to try a variety of interventions in a variety of ways. At times drugs may be helpful and at other times harmful. Interpretations of unconscious material may be contraindicated at certain phases of treatment and very helpful at others. The therapist must be eclectic, practical, and infinitely patient. He has to be willing to assume a greater degree of responsibility than is usually necessary in the treatment of less seriously disturbed patients. He must also recognize the important role of individual differences among therapists so as to find treatment methods that are effective for him. Ultimately, we have to be able to specify which therapeutic interventions alone or combined produce what specific changes in which specific patients under which specific conditions. Until we can do this, the treatment of schizophrenia remains at its best an intuitive art and at its worst a standardized obtunding of fellow human beings.

Norepinephrine Metabolites as Biochemical Criteria for Classifying Depressive Disorders and Predicting Responses to Treatment: Preliminary Findings

BY JOSEPH J. SCHILDKRAUT, M.D.

Preliminary findings suggest that levels of norepinephrine metabolites, particularly 3-methoxy-4-hydroxyphenylglycol (MHPG), excreted in urine may provide biochemical criteria for classifying at least some types of depressive disorders and possibly also for predicting the differential responses to treatment with various tricyclic antidepressant drugs.

THE POSSIBILITY that some depressions are associated with an absolute or relative deficiency of catecholamines, particularly norepinephrine, at functionally important receptor sites has been proposed on the basis of findings from basic as well as clinical neuropharmacological investigations (1–3). The validity of this hypothesis, however, remains to be definitively established. Several different biochemical mechanisms (e.g., a decrease in the output of norepinephrine from presynaptic neurons, an increase in the inactivation of norepinephrine, or a decrease in the sensitivity of postsynaptic receptors to norepinephrine) could conceivably cause the proposed deficiency of norepinephrine at receptor sites. Furthermore, it has been suggested that these different biochemical mechanisms might lead to differences in both clinical phenomenology and responses to pharmacotherapy (1, 4, 5).

This paper now reports preliminary findings that indicate that some depressed patients excrete relatively low levels of norepinephrine metabolites in the urine, whereas certain others excrete much higher levels. The findings, moreover, suggest that this may be a basis both for classifying at least some types of depressive disorders biochemically and possibly also for predicting the clinical response to treatment with the tricyclic antidepressant amitriptyline.

The author wishes to thank Paul R. Draskoczy, M.D., Peter Reich, M.D., Elliot S. Gershon, M.D., and Peter Wohlauer, M.D., for their collaboration in aspects of this work; and Edwin L. Grab, Pallas S. Lo, Patricia A. Platz, Carol R. Hicks, Barbara A. Keeler, Karen Bozogan, Gladys Rege, and the clinical staff of Service One for their assistance.

METHOD

Six patients, hospitalized for the treatment of depressive disorders, were studied longitudinally during the course of their illnesses. Depressions were classified according to clinical criteria described elsewhere (3). The question of a possible manic-depressive disorder was raised in two of the patients (U.R. and B.O.) because of hypomanic or manic episodes that occurred during the administration of antidepressant drugs or electroconvulsive treatments. Each patient's clinical state was assessed at least once a week by means of the Hamilton Depression Rating Scale (6) and the Mania-Depression Rating Scale (7).

Patients were not treated with psychoactive drugs for at least one week prior to beginning the collection of pretreatment data and during the pretreatment data periods. Following this period, treatment with amitriptyline was begun. A dosage of at least 75 mg. per day was attained in the first week and this was subsequently increased to at least 200 mg. per day for those patients who did not show a sustained response at lower doses. All patients participated in a program of interpersonal treatment throughout their hospitalization. Chloral hydrate (500 mg. per night) was administered for sleep to two patients (B.L.; S.G. for one night only).

Urine samples were regularly collected for 24-hour periods throughout the course of hospitalization. Levels of norepinephrine and epinephrine (8), normetanephrine (NMN) and metanephrine (9), 3-methoxy-4-hydroxymandelic acid (VMA) (10), 3-methoxy-4-hydroxyphen-

ylglycol (MHPG) (11), and creatinine (12) were all determined by modifications of previously described methods. Student's t test was used to determine the statistical significance of differences.

RESULTS

The pretreatment levels of norepinephrine and its metabolites NMN, VMA, and MHPG (expressed in micrograms per gram of creatinine) are presented in table 1. The levels of NMN, VMA, and MHPG were relatively low in three of these patients (E.S., K.F., and U.R.) and considerably higher in the other three (B.O., B.L., and S.G.). The differences in NMN levels were similar in magnitude to the differences we observed in an earlier study (13). The levels of epinephrine and its O-methylated metabolite metanephrine (which may also be converted to VMA and MHPG), did not show such marked differences among patients and did not appear to be related to the levels of the norepinephrine metabolites. The total excretion of norepinephrine and its metabolites showed a perfect correlation with age (see table 1).

Amitriptyline did not produce a sustained antidepressant effect (defined as a 50 percent or greater decrease in Hamilton Depression Rating Scale scores from pretreatment values that was maintained for at least six weeks) in any of the three patients with relatively low pretreatment levels of norepinephrine metabolites, although two of these patients (K.F. and U.R.) showed marked but transient improvements. (The transient improvements observed in patients K.F. and U.R. lasted for only two and five weeks, respectively, despite the continued administration of amitriptyline.) In contrast, all three of the patients with high pretreatment levels of norepinephrine metabolites showed rapid and sustained decreases in depression during treatment with amitriptyline (see table 1). Although a 50 percent decrease in the Hamilton Depression ratings was the criterion for improvement in this study, these three patients all showed considerably greater (i.e., 70 to 95 percent) decreases in their depression ratings.

VMA excretion was markedly decreased during treatment with amitriptyline (when compared with pretreatment levels) in all three patients with high pretreatment levels of norepinephrine metabolites, i.e., the three patients who showed rapid and sustained antidepressant effects (S.G., B.L., and B.O.). These differences were statistically significant ($p < .05$) in two of the patients (B.L. and B.O.) and approached significance ($p < .10$) in the third (S.G.). In contrast, significant decreases in VMA excretion were not observed during treatment with amitriptyline in the three patients with low pretreatment levels of norepinephrine metabolites, i.e., the three patients who did not show rapid and sustained antidepressant effects (U.R., K.F., and E.S.); see figure 1.

DISCUSSION

The present findings suggest that some depressed patients excrete relatively low levels of MHPG [1] and other norepinephrine metabolites in urine, whereas others excrete much higher levels. The low levels of norepinephrine metabolites observed in two of the patients (E.S. and K.F.) in this study suggest a decrease in both the synthesis of norepinephrine and its net output from

[1] MHPG is the urinary metabolite of norepinephrine that may provide the best available index of the synthesis and metabolism of norepinephrine (and normetanephrine) in the brain (14–16); however, MHPG may also be derived from norepinephrine originating in peripheral sympathetic nerves.

per Gram of Creatinine)

MHPG		Total*		Response to Amitriptyline

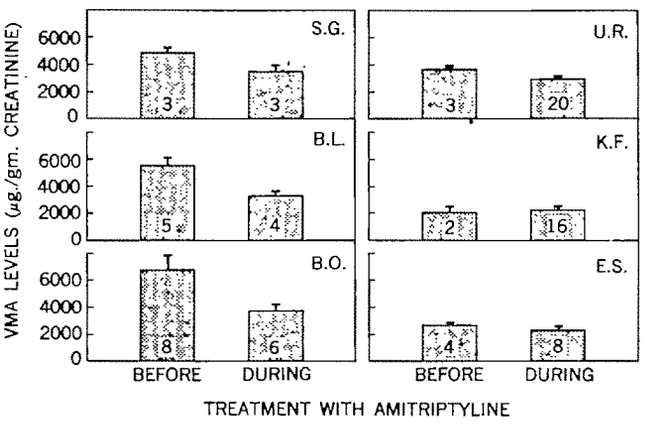
3	1140±40	3	4840±200	2	No
7	2240±200	7	8670±770	2	Yes
7	3190±230	5	8890±520	2	Yes
3	1590±210	2	6330±500	2	Yes

presynaptic neurons; a decrease in the neuronal discharge or an increase in the neuronal reuptake of norepinephrine would be compatible with these findings. The higher levels of norepinephrine metabolites observed in three of the patients (B.O., B.L., and S.G.) would be consistent with an increase in the enzymatic inactivation of norepinephrine or a deficiency in postsynaptic receptor sensitivity to norepinephrine that is partially compensated by an increase in the output of norepinephrine from presynaptic neurons; findings supporting each of these possibilities have been reported (17–19).

The two patients (E.S. and K.F.) with the lowest levels of MHPG and other norepinephrine metabolites had unequivocal diagnoses of manic-depressive depressions, i.e., bipolar disorders, whereas much higher levels were observed in the two patients (B.L. and S.G.) who had diagnoses of involutional or chronic characterological depressions. The highest levels of NMN and VMA occurred in the patient with an involutional depression (B.O.) who was overtly psychotic (paranoid); this is consistent with previous findings (9, 20). While the levels of norepinephrine metabolites appeared to bear some relationship to clinical diagnoses and phenomenology, this association is an imperfect one.

The total excretion of norepinephrine and its metabolites showed a perfect correlation with age in this series. In view of the small sample size, it is possible that this may have been a chance occurrence; however, other investigators have reported a positive correlation between normetanephrine excretion and age in psychiatric patients (21). It is, therefore, of some interest that the three patients who had the highest levels of norepinephrine metabolites and rapid and sustained responses during treatment with amitriptyline were older than the three patients who had lower levels and who did not show sustained responses to amitriptyline, particularly since it has been reported that amitriptyline is more effective than imipramine in depressed patients over 50 years of age (22) and that the activity of monoamine oxidase in human brain and peripheral tissues increases with age (23).



The present results show that amitriptyline decreased VMA excretion in the patients with high pretreatment levels of norepinephrine metabolites. In previous longitudinal studies of depressed patients, we found that VMA excretion was decreased during treatment with imipramine as well as with phenelzine (a monoamine oxidase inhibitor) (9, 24), and this finding has been confirmed by other investigators (19, 25, 26). Tricyclic antidepressants, including imipramine and amitriptyline, decrease the deamination of norepinephrine in animal brain (27–29), and the decrease in VMA excretion observed in patients during treatment with these drugs may similarly reflect a decrease in the deamination of norepinephrine by monoamine oxidase (9, 24, 30).

Further studies on a larger sample of patients will be needed to confirm these preliminary findings which indicate that there may be differences in the clinical and biochemical effects of amitriptyline in patients with low and high levels of norepinephrine metabolites. While one possibility, based on recent neuropharmacological findings, has been suggested to account for these differences (27, 30), many other factors will also have to be considered, including those related to age (22) or various clinical features (31) as well as to possible differences in monoamine oxidase activities in these two groups or differences in the metabolism of amitriptyline and its conversion to active (e.g., nortriptyline) or inactive derivatives. Moreover, the effects of amitriptyline on serotonergic neuronal systems may also be of importance in the clinical actions of this drug in some depressed patients.

Other investigators have recently reported that de-

FIGURE 1

*Excretion of VMA Before and During Treatment with Amitriptyline**

*The urinary excretion of VMA was determined before administration of amitriptyline and during treatment with this drug, beginning ten days after the start of amitriptyline administration. Data are plotted as means and standard errors of the means. The numbers within the bars indicate the number of samples analyzed.

pressed patients with low levels of MHPG excretion respond better to treatment with imipramine than do patients with higher levels of MHPG (26). In line with this observation, patient E.S. gave a history of having responded well to imipramine in a previous depressive episode and also showed a rapid response to imipramine when he again became depressed (during treatment with lithium carbonate) several months after his discharge from the hospital. Clinical experience indicates that some patients may respond to both imipramine and amitriptyline, whereas others may respond to neither; hence, there may be considerable overlap. Nonetheless, since the data reported here suggest that amitriptyline may be more effective in depressed patients with relatively higher levels of MHPG (and other norepinephrine metabolites), these preliminary findings, if borne out in our further studies (which will control for age and sex), may provide a rational basis for choosing between amitriptyline and imipramine in the treatment of patients with depressive disorders.

CONCLUSIONS

In summary, these preliminary findings in a small series of patients indicate that some depressed patients excrete relatively low levels of MHPG and other norepinephrine metabolites in urine, whereas certain others excrete much higher levels. Depressed patients with higher levels of norepinephrine metabolites showed decreases in VMA excretion and rapid and sustained clinical responses during treatment with amitriptyline, whereas patients with lower levels did not.

Although it is not possible to draw firm conclusions on the basis of these preliminary observations, which are based on a small number of subjects, the present results together with other recent findings suggest that the levels of the various metabolites of norepinephrine (particularly MHPG) excreted in the urine may provide biochemical criteria for classifying at least some types of depressive disorders and possibly also for predicting the differential clinical responses to treatment with amitriptyline or imipramine. This will be explored further in a large-scale controlled study.

Dreams as a Prognostic Factor in Alcoholism

BY SEI YOUNG CHOI, M.D.

This study tested the hypothesis that differences in both length of abstinence and demographic characteristics would be found between alcoholics who have dreams about drinking (DD group) and those who do not have such dreams (NDD group). The DD group was abstinent for longer periods of time; these patients were more often white, married, and taking disulfiram than were NDD patients. The author concludes that in outpatient treatment of alcoholics, dreaming about drinking is a good prognostic sign.

FREUD OBSERVED: "It is easy to prove that dreams often reveal themselves without any disguise as fulfilment of wishes. . . . For instance, there is a dream that I can produce in myself as often as I like—experimentally, as it were. If I eat anchovies or olives or any other highly salted food in the evening, I develop thirst during the night which wakes me up. But my waking is preceded by a dream; and this always has the same content, namely, that I am drinking. I dream I am swallowing down water in great gulps, and it has the delicious taste that nothing can equal but a cool drink when one is parched with thirst" (1, p. 123). Consistent with Freud's wish-fulfillment theory (1, 2), one might expect alcoholics who are abstaining from drinking to dream about drinking more than those who are not abstaining.

There are some data on dreaming among alcoholics. For example, in 1961 Moore (3) presented a paper on manifest dreams in alcoholism in which the only significant difference reported between alcoholic and nonalcoholic patients was the alcoholic's perception of himself as the victim of aggression or the object of punishment. The alcoholics showed a tendency (not statistically significant) to dream more of food, water, bottles, and pills; to see more male than female figures; to feel more anger, fright, and depression; to dream with less overt sexual content; and to feel less pleasure in their dreams. Hall (4) found that alcoholics had more dreams in which an oral incorporation occurred than did the nonalcoholics. Scott (5) noted that alcoholics dreamed more about drinking than did a control group.

These studies dealt especially with the manifest content of alcoholics' dreams compared with those of nonalcoholics. However, I have been unable to find any studies dealing with differences in dreams about drinking among alcoholics who had been abstinent for varying lengths of time. The purpose of this study is to investigate the importance of dreams about drinking in alcoholics who are in the process of therapy.

I advanced three hypotheses:

1. More alcoholics who have dreams about drinking (DD group) have been abstinent for at least three months than alcoholics who do not have dreams about drinking (NDD group).
2. More alcoholics who have been abstinent for at least a year have dreams about drinking than alcoholics who have been abstinent for less than a year.
3. The DD group differs demographically from the NDD group.

METHOD

The subjects were 100 alcoholics who attended the alcoholism outpatient clinic of Malcolm Bliss Mental Health Center in St. Louis, Mo. All the patients were being treated at the alcoholic day (1–4 p.m.) or evening (5–9 p.m.) clinic by the author for an average of 30 to 40 minutes of supportive psychotherapy and for an average of 10 to 15 minutes in the medication clinic, usually on a once-a-month basis.

The alcoholism diagnosis was based on findings of blackouts, "benders," impotence, a history of cirrhosis, tremors, and manifestations of delirium tremens associated with drinking; drinking patterns; impaired social adjustment; and subjective and objective feelings about drinking and damaged interpersonal relationships. These criteria are equivalent to the diagnostic criteria suggested by Feighner, Robins, and Guze (6).

Dr. Choi is Instructor in Psychiatry, Washington University School of Medicine, St. Louis, Mo., and Director of the Alcoholism Outpatient Clinic, Malcolm Bliss Mental Health Center, 1420 Grattan St., St. Louis, Mo. 63104.

TABLE 1
Significant Differences Between DD and NDD Groups

Item	DD Group (N = 50)	NDD Group (N = 50)	Significance
Abstinent more than three months	40	9	p<.001
Abstinent more than one year	24	5	p<.001
Abstinent longer than median of 92 days	34	9	p<.001

The 50 patients in the NDD group were randomly selected over a period of four weeks. The 50 in the DD group were collected within a five-month period. All were interviewed by means of a questionnaire form in which questions were asked about: a) the duration of complete abstinence, b) the presence or absence of dreams about drinking since abstinence, and c) the patients' feelings in the dreams and after they awakened.

RESULTS

Of the 100 patients who were interviewed, 81 were men (38 black and 43 white) and 19 were women (10 black and 9 white); all met the Feighner, Robins, and Guze criteria for the diagnosis of alcoholism. The ages of the 50 patients in the DD group ranged from 22 to 60, with a mean of 42.5 years; the ages of the 50 patients in the NDD group ranged from 23 to 69, with a mean of 42.3 years.

As shown in table 1, among DD alcoholics who had been abstinent for at least three months, 80 percent (40 of 50) had been abstinent for more than three months, while among the NDD alcoholics only 18 percent (9 of 50) had achieved more than three months' abstinence. This difference is highly significant (chi square = 38.45, df = 1, p <.001).

Eighty-three percent (24 of 29) of the alcoholics who were abstinent for more than one year were in the DD group, compared with 37 percent (26 of 71) of the alcoholics with less than a year of abstinence. This difference is also highly significant (chi square = 17.53, df = 1, p <.001).

The median number of days of abstinence in the total group was 92. The median split test showed that among the DD group, 68 percent (34 of 50) were abstinent more than 92 days, compared with 18 percent (9 of 50) in the NDD group. The difference was statistically significant (median test: chi square = 25.4, df = 1, p <.001). The average number of days of abstinence for the DD group was 358.9, while for the NDD group it was 111.8.

Demographic data including age, sex, race, education, marital status, use of disulfiram (Antabuse), and hours of sleep were analyzed (see table 2).

The difference between the DD and NDD groups' ages was not statistically significant. An examination of the average number of days of abstinence as a function of age showed that patients aged 50 to 59 remained abstinent for the longest time (603 days). Male patients in the DD group had periods of abstinence 3.4 times as long as those of male patients in the NDD group. Female patients in the DD group had periods of abstinence 7.3 times as long as those of female patients in the NDD group.

The average number of days of abstinence was smaller for black patients than for white patients. In addition, black patients were less likely to be in the DD group (33 percent of the blacks) than were white patients (65 percent of the whites). This difference is statistically significant (chi square = 10.25, df = 1, p <.01).

As shown in table 2, at all three educational levels the DD group had longer average periods of abstinence than the NDD group. Among the DD group the higher the education level, the longer the period of abstinence. This trend is not evident in the NDD group.

The patients who were married or single were more likely to be abstinent for longer periods of time than the separated, divorced, or widowed patients. The difference in marital status between the DD and NDD groups was statistically significant (chi square = 12.05, df = 3, p <.01).

There was a tendency for good sleepers (average 7.2 hours) to have longer periods of abstinence than poor or fair sleepers. This tendency was much more evident among the NDD group than among the DD group. In fact, poor or fair sleepers in the DD group had longer periods of abstinence than good sleepers in the NDD group. Poor sleepers (DD and NDD combined) were abstinent approximately half as long as good sleepers (average 292.1 days).

The medication (disulfiram) was used by 36 percent of the patients (16 males, two females) from the DD group, compared with ten percent (four males, one female) in the NDD group. The difference is statistically significant (chi square = 9.54, df = 1, p <.01).

Patients who drank alcohol in their dreams reported having the following feelings or behavior about their drinking: guilty feelings (eight percent), panic (eight percent), failure (four percent), anger (four percent), attempt to refuse drink (six percent), happiness (four percent), and fighting (four percent); 62 percent did not recall any feelings or behavior associated with drinking. However, after they awoke from their dreams of drinking, all of them felt glad, happy, or relieved after they realized they had not had anything to drink.

DISCUSSION

The data indicate that most alcoholics who have been abstinent more than three months have dreams about drinking. It is believed that approximately the first three months of abstinence in outpatient treatment constitute the period in which the alcoholic experiences the greatest struggle against his desire to drink.

The basis of this struggle is thought to be due to the

TABLE 2

presence of a wish to drink alcohol that has not been dealt with but has been mostly suppressed, denied, displaced, substituted for, or repressed. As a result, the individual's rejected wish for drinking from his consciousness becomes satisfied in his dreams. As long as he is able to satisfy his need to drink alcohol through a safe way (in his dreams), he has less internal (preconscious and conscious) anxiety, is able to deal with continuous internal and external stimulation about drinking, and can be abstinent for longer periods of time than those who do not have dreams about drinking. Particularly during the first three months of abstinence, alcoholics require more active, frequent contacts with counselors, social workers, and other professional staff members and an empathetic object relationship starting with the initial interview.

Older patients, who have less tolerance for alcohol and often more medical complications, may be able to tolerate greater amounts of anxiety associated with the temptation to drink. Thus both the DD and NDD alcoholic groups show a tendency toward longer periods of abstinence as a function of age.

Good object relationships may be one of the most important factors in a good prognosis for alcoholics. Patients with higher educational levels, stable marriages, and job stability have built up their ability to deal successfully with a variety of stressful situations. We could expect that this ability might be applied to the task of stopping drinking. Education may also help in another way: the more educated patients may have more insight and therefore might benefit more from therapy.

The findings regarding longer periods of abstinence and more dreams about drinking among whites compared to blacks may be explained by the general finding of greater marriage stability and higher educational levels among whites.

The influence of jobs on dream content and length of abstinence has not been investigated; however, job stability probably serves as an example of good object relationships. This will be investigated in future papers dealing with evening clinic patients who have jobs.

It is questionable whether the longer period of abstinence among good sleepers is due to their sobriety, or

vice versa. However, in the DD group, both good and poor sleepers were abstinent for approximately the same number of days and were abstinent longer than members of the NDD group, no matter how many hours they slept. This indicates that having dreams about drinking is much more important for prognosis than the quality of sleep.

Disulfiram therapy is important in treating alcoholics. It seems especially helpful to NDD patients, whose average number of days of abstinence was much greater with disulfiram than without. More male, white, 42-year-old, tenth-grade-educated, married good sleepers were likely to take disulfiram in both the DD and NDD groups. When questioned about their thoughts when they had cravings for a drink, all the alcoholics on disulfiram gave similar answers, such as "thought about the drug," "scared how sick I would be," or "What might happen to me if I drink on Antabuse?" Another interesting finding was that when alcoholics not on disulfiram who had long periods of abstinence were asked this same question, most of them said they thought about how sick they were when drinking. This was like a "self-aversive technique." It may be that alcoholics' self-aversive thinking is related to their spontaneous cure, but this will need further investigation.

Freud (1, 2) stated that he found undistorted wishful dreams principally in children, although short, frankly wishful dreams seemed to occur in adults as well. The present study shows that wishful dreaming occurs among alcoholics in the process of therapy.

Scott (5) stated that alcoholics dream more about drinking than do nonalcoholic controls. The present findings imply that it is those alcoholics who are able to abstain from drinking who do the most dreaming.

Scott also said that in his population of alcoholics who were attending a clinic, guilt accompanied the temptation to drink or the actual drinking in the dream in each instance; he attributed this guilt to clinic attendance. However, all the alcoholics in the present study were attending a clinic and most did not report guilt associated with dreams about drinking. In fact, only eight percent of the patients reported such feelings. All the patients felt glad, happy, or relieved after they awakened when they realized that their drinking had occurred only in their dreams.

Depersonalization, Dysphoria, and Thought Disturbance

BY G.J. TUCKER, M.D., M. HARROW, PH.D., AND D. QUINLAN, PH.D.

In a previous study the authors demonstrated a significant association between depersonalization and anxiety; in the present one they replicate this finding with an additional 152 patients and also delineate the close association of depersonalization with dysphoric affect and specific types of pathological thinking. From these data it appears that the patient who experiences depersonalization is a person with chronic anxiety, persistent depressive affect, and some degree of psychopathological thinking. It is hypothesized that depersonalization may then be the perceived feeling or experiential state of the person who has this constellation of symptoms.

DEPERSONALIZATION (the feeling of being distant and detached from the world—feeling strange or unreal) is a ubiquitious and complex symptom. Although depersonalization has been reported as a primary phenomenon (1), it is most often noted as one of the symptoms present in such diverse conditions as schizophrenia (2), depression (3), and neurosis (4). It is apparent that depersonalization feelings are widely reported and thereby

Dr. Tucker is Associate Professor of Psychiatry, Dartmouth Medical School, Hanover, N.H. 03755, and Drs. Harrow and Quinlan are Associate Professor of Psychiatry (Psychology) and Assistant Professor of Psychology, respectively, at Yale University School of Medicine, New Haven, Conn.

relatively nonspecific diagnostically; however, they retain a *uniqueness* and *consistency* as an *experiential state* that is of considerable theoretical and practical interest.

In a previous study we demonstrated many of the clinical correlates of depersonalization experiences (5). A clearer picture of how we use the construct "depersonalization" may be gained by examining the questions used to determine the presence of depersonalization in the previous and present studies:

1. Have you ever had the feeling you may be two people—one going through the motions while another "you" is observing?
2. Have you ever had the feeling that there was a wall or veil between you and other people?
3. Have you at any time experienced the feeling that you were unreal?
4. Do you ever feel like a stranger to yourself?

Even though these questions are embedded in a more detailed questionnaire, we have been impressed with several aspects of the responses to these questions by well over 300 psychiatric patients. First, depersonalization is a distinct experience that seems to be immediately apparent to people who have experienced it when they are questioned about it in this manner. Secondly, depersonalization is primarily an *inner feeling state*, not necessarily denoting feelings about the body or the "body image" (6). Although depersonalization and the construct of the body image have been used interchangeably by clinicians, there is little experimental or clinical evidence to justify the frequent interchangeable use of these terms (7–9). Thus, if we accept the symptom of depersonalization as primarily an inner feeling state then it follows that it may be present in many emotional states, both pathologic and normal, rather than being associated with only one specific type of psychopathology.

In a previous study we demonstrated the close association of depersonalization and anxiety. In the research reported here we attempted to replicate our previous finding and to examine two other potential aspects of the depersonalization experience that seem theoretically and clinically pertinent—specifically, the relationship of depersonalization to depressive feelings and cognitive disturbances.

METHOD

The presence of depersonalization phenomena was elicited by means of a questionnaire whose derivation and validation were previously described (5). The questions were scored on a 1–5 scale of frequency of occurrence and a total score denoting frequency of depersonalization feelings was recorded for each patient. This questionnaire was administered to 155 consecutive admissions to the Yale-New Haven Hospital (10, 11), none of whom had been used in our previous research. Thirty-eight percent of the sample were men and 62 percent were women; the median age was 25 years. The diagnostic distribution is described in table 1.

Three types of data were collected. 1) Observer ratings (table 2) were used that have been utilized in previous studies (12, 13). 2) Various standardized self-report scales (table 3) that were particularly directed at depressive symptomatology were used. These included the Zung Depression Inventory (14) and the Depression Mood Scale from the Zuckerman Multiple Affect Checklist (15). Since a wide number of tests based on patients' self-reports were administered, two additional scales were given to assess whether test-taking attitudes were unduly influencing the results in this area. These two scales designed to assess certain test-taking attitudes were the Lie scale of the Maudsley Personality Inventory (16) and the Marlowe-Crown Scale (M-C) (17) to assess the influence of social desirability. The correlation between depersonalization scores and the Lie scale was $r = -.14$ (nonsignificant), and that between depersonalization and the M-C scale was $r = -.25$. Since the correlation with the M-C scale was significant, partial correlations to control for social desirability were calculated (table 3) for all subsequent correlations between depersonalization and self-report scales that were significant. 3) The Rorschach test ($N=60$) and the Object Sorting test ($N=150$) were administered to random subsamples of the patients to assess thinking disturbances. Indices used in these latter two tests have been described by us previously (25, 26). An additional sample of 111 patients similar in composition to the main sample was tested at weeks one and four of hospitalization to assess change over time.

TABLE 1
Distribution of Depersonalization Scores According to Diagnosis (N = 155)

Diagnosis	Depersonalization		
	Minimal	Some	Considerable
Personality disorder	12	4	13
Neurotic depression	10	3	6
Psychotic depression	9	4	9
Latent schizophrenia	8	2	21
Classical schizophrenia	13	6	21
Other (including manic patients)	11	2	1
Total	63	21	71

Diagnosis was established by two senior clinicians according to the second edition of APA's *Diagnostic and Statistical Manual of Mental Disorders*. These clinicians did not have access to any of the other data collected in this study. The data were examined for the frequency of each variable, and the correlations of depersonalization with other aspects of psychopathology were obtained.

RESULTS

Depersonalization and Dysphoric Affect

Using a number of different indices (table 3), the data strongly indicate that patients who experience deper-

TABLE 2
Correlation of Observer Ratings with Depersonalization Scores

Psychiatrist's Ratings	Number	Correlation
Guilt	145	r = .04
Depression	127	r = .18*
Isolation	143	r = .23**
Withdrawal	143	r = .27**
Delusions	52	r = .02
Suicide attempts	132	r = .12

*p < .05.
**p < .01.

sonalization phenomena have *significant amounts of dysphoric affect.* Partial correlations to control for test-taking attitudes (the M-C scale) are presented for all significant correlations in this section, and the results are substantially the same. Thus there were significant correlations with: 1) the Zung Depression Inventory (14), 2) the Zuckerman scales for depression and anxiety (15), 3) scales assessing thought and motor retardation (18), and 4) a modified Q-Sort scale we have used previously to assess self-concepts (19). The Q-Sort data showed that these patients have markedly negative self-images. The Semantic Differential (19) confirmed this and demonstrated significantly lower degrees of self-evaluation; however, this was not true of the patients' ratings of themselves on scales for potency and activity.

On a wide range of symptoms assessed by various scales used by Srole and Brimm (21–23), the patients with depersonalization phenomena manifested less optimism and self-confidence (22) and more anomie and frustration (23). These patients did not show diurnal variations in their mood, nor was there a significant relationship to attempted suicide. In this respect, it is of interest that patients who scored high on depersonalization were not necessarily patients who had a primary depressive diagnosis. Formally diagnosed depressives even tended to score somewhat low on depersonalization. However, all of the patients were also rated for secondary depressive features (mainly affect) by the two clinicians and there was a tendency ($p < .10$) for patients who are classified as having significant amounts of depressive symptomatology, but who are given other primary diagnoses, to score higher on depersonalization. Many of the patients with depersonalization phenomena were also noted to have major hysterical features in their presenting clinical picture ($p < .05$), suggesting a relationship with anxiety and other neurotic features.

Depersonalization and Thinking

In evaluating the relationship of depersonalization to thought processes, two specific aspects of the responses to the Rorschach were considered. The first surveyed the scores indicating general disorganization of thinking, while the second assessed those aspects of thinking and perception related by Landis to "extreme permeability" of conceptual boundaries (27). The first aspect of general disorganization in thinking on the Rorschach used in this study was a composite scale of the following measures: 1) extremely deviant indications of idiosyncratic thinking and autistic logic, 2) elaborations in affective terms, and 3) overly specific or overly general elaboration ($N = 60$, $r = .35$, $p = < .01$) (25). This relationship indicates that depersonalization occurs more frequently in persons with high levels of extremely disorganized thinking, but the relationship is by no means so strong as to preclude the occurrence of depersonalization in less disorganized states.

The second aspect of Rorschach responses used was another composite measure of conceptual boundary difficulty that consists of: 1) fabulized combinations, 2) contamination tendencies, and 3) full contaminations. The significant correlations ($N = 60$, $r = .28$, $p = < .05$) with this scale demonstrated that patients with depersonalization manifest extremely permeable boundaries between concepts, at least as manifested by their Rorschach responses. Even when only the most extreme responses indicating conceptual boundary difficulty (contaminations) were used, the relationship between high boundary dissolution and depersonalization was significant.

While the above boundary measure relates more clearly to conceptual boundaries, another Rorschach scoring system, for Barrier and Penetration, has been more clearly related to the "body image" concept (28). The Barrier ($N = 60$, $r = .04$, $p = $ n.s.) and Penetration ($N = 60$, $r = .22$, $p = $ n.s.) scores did not relate to depersonalization. Federn's suggestion that depersonalization involves a disturbance of ego boundaries (29) is partially supported, but the evidence from the Rorschach suggests that this may be related to a more pervasive general disturbance of thinking. The present data may be partially biased by the large number of schizophrenic patients in the sample. However, Shorvon (1) evaluated the Rorschach protocols of 66 patients, none of whom were clearly schizophrenic but who had severe depersonalization symptoms. They seemed to manifest more severe psychopathologic thinking than other patients, as we have found in the present sample. The data from the object sorting test showed no significant correlations (behavioral overinclusion, $r = .07$; idiosyncratic thinking, $r = .05$; conceptual overinclusions, $r = .00$; N for all = 149). While it is a distinct possibility that the Object Sorting test is actually measuring another aspect of thinking (26), this lack of a significant correlation does call for caution in the interpretation of the Rorschach data until further replication.

Depersonalization Symptoms Over Time

To examine changes in depersonalization as acute symptomatology subsides in psychiatric patients, we administered the depersonalization scale to an additional sample of 111 acute psychiatric patients at week one of their hospitalization and then readministered the scale at week four. There were no significant differences between the depersonalization scores at week one and those at week four. In several previous studies, using samples similar in composition to those in the present one, we have

shown that a great deal of acute symptomatology had diminished by the fourth week of acute hospitalization (30). The present data indicating that depersonalization scores had not diminished significantly suggest that, while depersonalization is related to other acute symptoms, it may take a number of weeks before this symptom diminishes significantly.

Relationship Between Depersonalization and Variables Examined in Previous Research

Many of the trends noted in our previous study were reconfirmed, such as high correlations with various tests of anxiety, e.g., the Taylor Manifest Anxiety (24) and the Neuroticism scale of the Maudsley Personality Inventory (16). There were no significant correlations with delusions or hallucinatory phenomena (see table 2). Patients reporting depersonalization scored particularly low on questions relating to suspiciousness and paranoia, and the previously reported (5) relationships to age and sex (i.e., depersonalization is more common in young people but is not related to sex) were replicated in the present sample.

The previously noted positive association between schizophrenia and depersonalization phenomena (5) was also present in this sample, particularly in those patients given a latent or borderline schizophrenic diagnosis. Thus the latent schizophrenic group scored significantly higher on depersonalization ($p < .05$) than the combined depressive group (patients formally diagnosed as either neurotic or psychotic depressives), and the classical schizophrenic group tended to score higher on depersonalization (although the comparison was nonsignificant) than the combined depressive group.

TABLE 3

Correlations for Personality Scales, Mood Level Items, and Depersonalization

Scale	N	Correlation with Depersonalization	Partial Correlation with Marlowe-Crown Scale (17)

DISCUSSION

From these data and previous studies, the picture of the patient who experiences depersonalization is that of a person with chronic anxiety, persistent depressed affect, and some degree of psychopathological thinking. These symptoms cut across many diagnostic categories. This is true of depressive feelings and anxiety, and possibly of certain types of thinking disturbances. It may be that the ubiquity of the depersonalization experience is due to its being an epiphenomenon of these prominent and somewhat pervasive symptoms. As such, depersonalization may be viewed as a "signpost" that the noted group of symptoms could be present, e.g., anxiety, depression, and thinking disturbance. Depersonalization may be one of the feelings or experiential states perceived by the patient who has this constellation of symptoms.

It is conceivable that the categorization into various diagnostic groups of "mental illness" may be related to the type and degree of manifestation of these basic symptoms, e.g., depression, anxiety, depersonalization, disturbed cognition, social withdrawal. The appropriate label is then affixed depending upon the emphasis placed on particular symptoms by either the clinician or the patient. In part this was noted by Aubry Lewis in his classic paper on melancholia: "It is not only that unreality appears elsewhere than in depressive states; it is not only that it is a part of a general relation of the personality to the environment; it is also a token of the essential likeness between clinical states, generally regarded as either opposed or dissimilar" (31, p. 336).

In general we seem to be dealing with a chronic experience of discomfort of the self in the world. The important components of this symptom seem to be related to a constellation of other symptoms, including depressed affect, anxiety, and possibly certain types of disturbances of

thinking. The present data do not provide evidence on whether this is a preformed response of the brain, as noted by Mayer-Gross (32), or a psychologic shutting out of the world due to life experiences (29). However, the constant association of these symptoms in this and other studies, particularly depressed affect and anxiety (5, 8, 31), seems to delineate a certain core symptomatology in what we are presently calling mental illness. This core symptomatology is probably related to what might be labeled a chronic depressive character (13).

Marijuana and Amphetamine: The Question of Interaction

BY STEVEN ZALCMAN, M.D., BARRY LISKOW, M.D., REMI CADORET, M.D., AND DONALD GOODWIN, M.D.

Animal studies have indicated that marijuana has both a depressive and an excitatory effect on the central nervous system. Since drug users occasionally combine marijuana and amphetamines, a study was performed to determine whether the two drugs have an interaction effect on a variety of physiologic and psychological measures. In general, no such interaction was demonstrated. Previously reported physiological effects of marijuana and amphetamines were confirmed, although some of the psychological effects were at variance with previously reported findings.

MARIJUANA IS generally regarded as a central nervous system depressant. Yet it has been reported that tetrahydrocannabinols potentiate amphetamine-induced hyperactivity as well as hexobarbital sleeping time in animals (1, 2). Because there is evidence that drug users may use marijuana and amphetamines simultaneously (3), we were interested in determining whether the two drugs are synergistic in humans. A previous study (4) evaluated responses to marijuana, marijuana placebo, and dextroamphetamine administered separately to human volunteers. In the present study, marijuana, dextroamphetamine, and placebos were administered separately and together in a factorial design in order to investigate interaction effects.

METHOD

Ten adult males (ages 21–28) were subjects on four occasions. The selection criteria were: 1) chronic use of marijuana, defined as use of the drug more than 50 times; 2) occasional use of oral amphetamines without a history of chronic abuse or intravenous administration; 3) absence of physical and psychiatric illness; and 4) agreement of the subject to abstain from all drugs during the course of the experiment.

At the time this study was performed, the authors were all with the Washington University School of Medicine, 4940 Audubon Ave., St. Louis, Mo. 63110, where Dr. Zalcman was a fourth-year medical student, Dr. Liskow was a Resident in Psychiatry, and Drs. Cadoret and Goodwin are Associate Professors of Psychiatry. Address reprint requests to Dr. Goodwin.

This work was supported in part by Public Health Service grants MH-09247, MH-05804, and MH-12087 and Research Scientist Development award MH-47325 (to Dr. Goodwin) from the National Institute of Mental Health.

The authors wish to thank Leo Hollister, M.D., for providing some of the psychometric tests employed in this study.

The four experimental conditions in the factorial design for each subject were: 1) placebo marijuana, placebo amphetamine; 2) placebo marijuana, amphetamine; 3) marijuana, placebo amphetamine; and 4) marijuana, amphetamine. The order of the experimental conditions was randomly assigned and unknown to the subjects and observers. Each subject was tested at weekly intervals in the morning, after having fasted. On each occasion the subject was given a control battery of tests, drank 250 cc. of a noncaloric soft drink containing either 15 mg. of dextroamphetamine sulfate or no drug, smoked two 500 mg. marijuana cigarettes that contained either placebo material or 1.5 percent delta-9-tetrahydrocannabinol (THC),[1] waited 90 minutes, and was given a second battery of tests.

The test battery measured physiological and psychological parameters. Physiological measures included blood pressure, pulse, respiratory rate, pupil size, and conjunctival injection.[2] The psychological tests included the Digit Symbol Substitution test, the Digit Span, the Mood Adjective Checklist, the Number Facility and Flexibility of Closure tests, and a subjective rating of hunger.

The Digit Symbol Substitution test, a subtest of the Wechsler Intelligence Scales testing cognitive function, was scored for the number of correct substitutions made in 90 seconds. The Digit Span, another Wechsler Scale subtest, tests immediate recall and capacity for simple abstraction (the ability to repeat numbers backwards). It is scored as the sum of the forward and backward digit spans. The Mood Adjective Checklist consists of 27 adjectives describing current mood states, rated on a four-point scale from "not a bit" to "extremely." Scores were obtained for three factors: an "active" factor, a "drowsy" factor, and a "stimulation" factor. This scale has been shown to successfully distinguish between active and placebo amphetamine regimens solely on the basis of subjective criteria (6). The Number Facility test consists of 90 simple addition problems and the Flexibility of Closure test consists of 36 line figures that the subject must reproduce in an adjacent field of dots (7). Both tests have numerous equivalent forms, so that no subject received the same form twice. The subjects were allowed to

[1] Lot no. 2-PF-81, supplied by NIMH, which assayed it for delta-9-THC content. We confirmed their results at the conclusion of the experiment by analyzing a sample according to the method of Lerner (5).

[2] Pupil size was measured with the Rosenbaum Pocket Vision Screener under conditions of constant illumination and focal length. Conjunctival vessel dilation was rated from 0 to 4, with 3 and 4 indicating marked vascular congestion.

complete the entire form for these two tests, permitting scoring of both the number correct and the time required. Hunger was rated on a ten-point scale, with 1 representing no hunger and 10, intense hunger.

RESULTS

The mean differences between the predrug and postdrug values on all parameters were calculated for the four experimental conditions for each subject. These data were then subjected to analysis of variance as a 2 × 2 factorial design. Physiologic measures showed several significant main effects for either amphetamine or marijuana, but no significant interactions. The pulse rate was significantly increased by marijuana ($p < .01$), which is consistent with previous reports (8). The pulse rate showed no detectable amphetamine or interaction effect. Systolic and diastolic blood pressure were increased by amphetamine (systolic, $p < .01$; diastolic, $p < .05$); neither a marijuana nor an interaction effect was noted. The respiratory rate was unaffected by marijuana but it was increased by amphetamine ($p < .05$), again without discernible synergism or antagonism. Pupil size was unaffected by either drug. Conjunctival vessels were dilated by marijuana ($p < .01$), but showed no amphetamine or interaction effect.

Performance on the Digit Symbol Substitution test has been reported to be improved by amphetamine (4), to be decreased by marijuana in naïve users (8), and to show a trend toward improved performance after marijuana in chronic users (8). Analysis of our data revealed a trend toward poorer performance by chronic users after marijuana that closely approached significance at the $p < .05$ level. There was no significant amphetamine or interaction effect.

Performance on the Digit Span was decreased by marijuana ($p < .05$). Once again amphetamine failed to alter performance, either alone or in conjunction with marijuana.

Hunger, as detected by our subjective rating scale, was decreased by amphetamine ($p < .01$) but not otherwise affected. This is an interesting finding in view of the hunger and hyperphagia that are often reported to follow marijuana use.

The Flexibility of Closure results were not significant for the number correct or the time required. The results of the Number Facility test were not significant for the number correct for either drug. The time required for this test, however, was decreased by amphetamine ($p < .01$), increased by marijuana ($p < .01$), and decreased by the mixed regimen ($p < .05$).

The three "mood factors" were analyzed, comparing the predrug scores with the scores at two hours and two and three-quarters hours after drug ingestion. The "active" factor was not affected by either drug, in contrast to Hollister's finding that amphetamine increased "activity" and marijuana decreased it (4). The "drowsy" factor was decreased by amphetamine ($p < .01$), but no marijuana effect was noted. The "stimulation" factor was increased by amphetamine ($p < .05$ at two hours, and $p < .01$ at two and three-quarters hours). For none of the three factors was there evidence of drug interaction.

DISCUSSION

The effects of these two drugs on the physiologic parameters were consistent with those in previous reports. Marijuana resulted in tachycardia and conjunctival injection, while amphetamine increased blood pressure and the respiratory rate. Pupil size was unaffected by either agent, and there was a lack of evidence for drug interaction.

The results of the psychological tests were more equivocal and not always consistent with previously reported findings. This might be explained by differences in drug dosage. Earlier reports have failed to stipulate how long before the completion of their experiments the marijuana was analyzed, and it may have subsequently deteriorated. There are also certain methodological differences. Our analyses involved comparing predrug and postdrug performances on the same day. Hollister (4) tested his subjects only after drug administration, with placebo marijuana administered on a separate occasion that served as a baseline.

With regard to drug interaction, the only hint of this concerned the time required for completion of the Number Facility test. Amphetamine improved performance, marijuana worsened it, and the combination resulted in an intermediate score with amphetamine improvement predominating.

On the basis of these results, it would appear that marijuana and amphetamine act independently in man insofar as their effects can be determined by the tests employed in this study. This by no means precludes the possibility that different indicators would disclose such an interaction. It should also be noted that the dosage levels of THC used in the animal studies showing synergism with amphetamine were quite high (up to 25 mg./kg.) and that the behavior observed (motor activity) is not strictly comparable with the parameters measured in this study.

The Relationship Between Background and Extent of Heroin Use

BY LT. STEVEN F. BUCKY, MC, USNR

The backgrounds of individuals who had used heroin fewer than five times and those who had used it six or more times were studied to determine if there were any significant differences. The subjects were Navy enlisted men who were given an anonymous questionnaire. Significant differences were found: in general, more extensive heroin use was related to poorer relationships with family as well as more difficulties in school and in the Navy.

IN A STUDY REPORTED in 1971 (1) comparing nonusers and marijuana, amphetamine, LSD, and heroin users, I found that compared to the other groups, the heroin users had significantly more difficulty at home, in school, in marriage, and in the Navy. Using the multiple correlation technique, 15 variables combined to correlate at .67 with the criterion of heroin use.

A number of variables contributed to this high correlation. There was a significant positive relation between heroin use and expulsion or suspension from school, arrests, disciplinary action by the Navy, and the mother's education and drinking habits. Other variables that were positively related to heroin use were the father's drinking habits and education and the subject's education. There was a significant negative relationship between heroin use and the mother's smoking habits and the subject's age. Many of the fathers of this group were not living. Other variables that negatively related to heroin use were family income, the father's smoking habits, and courts martial. The subjects were frequently firstborn or only children.

Other research (2) described heroin users as narcissistic and passive-dependent. Torda (3) described them as being subject to magical thinking and daydreaming. They were extremely mistrustful, in a way that bordered on paranoid projection. Torda also found that for the heroin addict, the mother represented authority; overt aggressive behavior on the part of the addict was intolerable. The father of the heroin user was frequently absent; when present, in many cases he was an alcoholic. The addict was usually the favorite child of the mother, although she was often unable to express genuine love for him. The subjects in the study usually experienced complete helplessness and worthlessness, with very low frustration tolerance. They were also described as hypersensitive, masochistic, and as loners.

Hekimian and Gershon (4) described the heroin user as sociopathic and as desiring the euphoria from the drug to control his underlying intense depression. These authors also found the heroin addict to be passive. Steffenhagen and associates (2) found that the heroin addict had a profile consistent with that of the sociopath. Heroin addicts also revealed much more pathology on the Minnesota Multiphasic Personality Inventory than subjects using other drugs.

Although, as previously noted, a multiple correlation of .67 was obtained in my previous attempt to predict heroin use, it was felt that for a more conclusive prediction one must discriminate the individual who has just tried heroin and has decided to discontinue its use from the individual who uses the drug regularly. In an attempt to distinguish between the "experimenter" and the more extensive user, the present study compared 42 social history variables for individuals who reported having used the drug five or fewer times with those who had used it more than six times.

METHOD

The subjects were 42 Navy enlisted men who were stationed at one of five bases in the Pensacola, Fla., area. Twenty-three of the subjects reported having used heroin five or fewer times (Hexp group); 19 subjects had used the drug more than five times (H group). The subjects were identified as heroin users from a questionnaire that was given anonymously to 1,508 subjects.

The questionnaire was a modification of the standardized psychiatric interview questionnaire given to all inpatients and outpatients at the Naval Aerospace Medical Center at Pensacola. Instead of using the open-ended questions, each item was reworded in multiple-choice form so that it could be easily analyzed by a computer. There were 42 items, 12 of which pertained to specific drug use. Eighteen items focused on the subject's parents and siblings, two on his education, three on legal difficulties, three on his marital status, and three on his military background; the other asked the subject's age.

RESULTS

As shown in table 1, the results indicate that there were significant differences between the Hexp and the H groups.

Opinions expressed herein are those of the author and do not necessarily reflect the views of the Department of the Navy.

TABLE 1
Comparison of Heroin Users and Experimental Heroin Users, in Percentages

Variable	Heroin Users	Experimental Heroin Users
Has taken drugs for at least five years	53	32
Fair-to-poor relationship with father	42	31
Fair-to-poor relationship with mother	37	18
Fair-to-poor relationship between parents	22	47
Mother and father are not living together	74	52
Was truant	95	78
Was suspended or expelled from school	80	60
Was arrested	82	65
Went before captain's mast	78	52
Was court-martialed	24	21

The subjects in the H group were generally older. As for other drug use, the subjects in the H group had used marijuana, amphetamines, and barbiturates to a lesser extent, although they had used LSD more than had the Hexp group. It is interesting to note that there was very little difference between the groups in terms of whether the subjects had used the various drugs in a group or alone, with the exception of heroin. The H group used that drug more often in group settings than did the Hexp group. The subjects in the H group had started to take drugs because "it felt good" or because of an association with a friend on drugs. In contrast, the Hexp group did not know why they had started or the reason was other than those described above. The H group also reported having been on drugs for a longer period of time than the Hexp group.

In an analysis of the subjects' family backgrounds, it was found that the fathers of the H group were younger and had more education than those of the Hexp group. The subjects in the H group had poorer relationships with their fathers. Less heavy drinking was reported for the fathers of the H group; no difference was observed in terms of the fathers' smoking.

The mothers of the H group were older than those of the Hexp group; no difference was observed in terms of their education. The relationship between the mother and son was described as being poorer; there was more heavy drinking and smoking among the mothers of the H group than among those of the Hexp group.

It is particularly interesting to note that in spite of the poor relationship between father and son and mother and son, the relationship between the parents (when they were still living together) of the H group was better than that of the parents of the Hexp group. Nevertheless, for the H group there were fewer parents living together and more deceased fathers and mothers; also, more subjects reported that they did not know whether their parents were living or dead than in the Hexp group.

As for socioeconomic variables, there were more laborers and farmers and fewer managers, sales workers, service workers, and craftsmen among the parents of the H group; nevertheless these families had higher family incomes than the families of the Hexp group.

The subjects in the H group came from larger families and were more often the youngest children in the family. They had completed more schooling but graduated at an older age and were more frequently truant, suspended, expelled, or arrested during their school years than the subjects in the Hexp group.

The subjects in the H group had more divorces and more children than those in the Hexp group. They had been in the Navy longer and had been more often to captain's mast (disciplinary action) and had more courts martial than the Hexp group.

DISCUSSION

There are numerous limitations in the present study: 1) the operational definitions of the "more extensive user" and the "heroin experimenter" are arbitrary; 2) there are too few subjects; and 3) it is virtually impossible to evaluate the validity and honesty of the subjects' responses to the questionnaire. Nevertheless, these results combined with my previous findings suggest that there are differences between heroin users and other drug users or nonusers, and more specifically between the long-term heroin user and the individual who has tried the drug and either discontinued its use or gone on to other drugs. All of these factors are seen as important in the ultimate prediction and prevention of heroin use.

The Psychiatric Treatment of the Geriatric Patient

BY ROBERT J. NATHAN, M.D.

The author demonstrates, through case examples, how geriatric patients can be integrated into a general hospital's intensive therapeutic milieu program. He points to the need for further investigation of the advisability of segregating these patients from the general psychiatric population, as is now commonly done; perhaps other approaches will prove more fruitful.

DISCUSSION OF THE psychiatric treatment of the geriatric patient is usually so fraught with pessimism and hopelessness as to make most practitioners within psychiatry extremely leery of any involvement at all with these patients. Notwithstanding literature to the contrary (1), the consensus among practicing psychiatrists is that the geriatric patient presents very little in the way of therapeutic possibilities. In this paper I will present evidence that geriatric patients with both functional and organic factors operative in their mental illness can indeed be restored to reasonably satisfactory function by the use of the facilities of a general hospital's small psychiatric unit which employs the principles of the intensive therapeutic milieu-therapeutic community (2, 3). The patients to be considered are three of a series of at least 39 patients; I will describe them in some detail.

BRIEF HOSPITALIZATION IN AN INTENSIVE THERAPEUTIC MILIEU

Case Reports

Case 1. K.W., a 68-year-old woman, had been living in a nursing home for approximately three years, had had intermittent psychotherapy during that time, and was rehospitalized in April 1971 with complaints of anorexia, insomnia, moderate disorientation, and an obsessive-delusional idea that all the people in the nursing home were interested in forming a sexual liaison with her. In addition to this, when she went to bed at night she was convinced that rodents were crawling over her bed and nibbling at her, especially at her genitalia.

Case 2. R.J., a 73-year-old man, was hospitalized for manic behavior that had been going on for approximately six months. He lived in an apartment with his wife. He was getting substantial loans from banks, had rented an apartment for himself in a nearby city, was engaged in writing "the great American novel," and had periods of angry outbursts against his wife. He claimed to feel very good and certainly much better than immediately prior to the onset of his manic illness, when he was tired. His only previous psychiatric history consisted of a short hospitalization about eight years before his apparent manic episode. In this man's mental status examination lapses of memory were extremely common, and there was some disorientation as to date and place.

Case 3. D.F., a 72-year-old woman living in a retirement home, had had periodic depressions for approximately eight years requiring hospitalization in two institutions, with electroshock therapy given both times. Her symptomatology at the time of the hospitalization described here consisted of anorexia, insomnia, obsessive concern over money, and a delusional belief that she had cancer of the bowel, which was made evident to her because of her severe constipation. In addition to this, she claimed to have stopped urinating and this, too, was evidence of her cancer. In addition to these symptoms the patient had been showing definite memory lapses.

All three of these patients were admitted, at different times, to the Hahnemann Inpatient Unit, a 14-bed psychiatric unit located within Hahnemann Hospital. As previously noted, the ward uses the techniques of the intensive therapeutic milieu. The average length of stay is approximately 14 days. The unit is completely heterogeneous regarding age, race, and social class. In addition to serving as a resource for referral of private patients, it also serves as one of the inpatient units for the Hahnemann Community Mental Health Center. The only age restrictions are those at the younger end of the scale; only rarely will patients below the age of 15 be admitted. At no time does the unit have a preponderance of geriatric patients; the most at any given time is three or four.

The unit itself provides a five-day-a-week "milieu" meeting that lasts for approximately an hour and involves all the staff and all the patients in the unit. The content of this meeting ranges anywhere from discussion of problems of living on the unit to discussion of particular patients and their particular problems in relation to the group. A fair amount of attention is paid to the communicative meaning of symptomatic behavior and its clarification. This meeting is the central focus of the day's therapeutic activities; and, as with almost all of the other activities on the unit, all patients must participate.

In addition, there is group art therapy and group recreational therapy on a daily basis, role playing on a weekly basis and, for patients for whom it is judged applicable, individual psychotherapy and pharmacotherapy as well.

The stated expectation of this unit is that it will return a hospitalized patient to his community within two to

Read at the 125th annual meeting of the American Psychiatric Association, Dallas, Tex., May 1–5, 1972.

Dr. Nathan is Director of Partial Hospitalization and Inpatient Services, Hahnemann Medical College and Hospital, 314 North Broad St., Philadelphia, Pa. 19102.

three weeks and that his psychiatric behavior will have been sufficiently altered so as to allow him to remain in the community. It is recognized that this is not a definitive treatment and that follow-up psychotherapy is absolutely essential. This is stressed throughout the patient's hospital stay. Virtually all hospitalized patients, including those privately referred, are treated by the psychiatric staff. The staff consists of a Board-certified psychiatrist and graduate psychoanalyst who is chief of the inpatient service, two first-year residents in psychiatry, a social worker, a part-time psychologist, approximately 14 nurses, an art therapist, and a recreational therapist. As with any such operation, there are frequent meetings held among members of the staff to discuss the patients. In general, the unit has been functioning at or above the level at which it was originally intended.

The staff was initially reluctant to accept geriatric patients on a regular basis. It was felt that the milieu was constructed primarily for the younger patient and that the older patient would tie up the staff for long periods of time in making dispositions, thus draining off the direct therapeutic interest that the staff had. In addition, the staff tended to feel that geriatric patients almost universally have a significant degree of chronic brain syndrome, which would make any treatment they could offer ineffective.

This pessimism can be seen in case 1. When this woman was admitted it was felt that her primary diagnosis was that of a psychotic depression and that she could best be treated with massive doses of antidepressants. She was placed on a moderately high dose of imipramine hydrochloride (Tofranil), which promptly resulted in her becoming so organically psychotic that she literally did not know where the bathroom was and began wandering throughout the general hospital. Thus the self-fulfilling prophecy appeared to be in operation. However, the chief of the service recognized what in fact was happening and reduced the medication. To the amazement of all, the patient's organic psychosis began to clear up, and she began to participate in activities on the unit. Within 17 days she was discharged to her nursing home; she was eating and sleeping well and was free of delusional and obsessional symptoms.

The patient in case 2 was placed on small amounts of medication, and although small signs of organic impairment were seen, Mr. R.J. never developed a full-blown organic psychosis. He was eventually placed on lithium carbonate, but had markedly calmed down prior to that medication. He was well accepted into the group with the younger patients, and after about 16 days was discharged to his home.

Mrs. D.F. was admitted in a state of severe depression and remained so for approximately three weeks, with little or no participation within the group or interaction with other patients. When this reaction was noted and analyzed within the group setting, there was a gradual loosening up of the patient's aggressivity, she began verbalizing more easily, and after about five weeks she was discharged to her retirement home. She had been receiving moderately large doses of phenothiazines but had not developed any further organic symptoms.

All three of these patients were observed by psychiatrists following their discharge and appeared to be doing reasonably well.

DISCUSSION

The model upon which the Hahnemann Inpatient Psychiatric Unit was based is fully described by Artiss (2, 3). His patient population consisted of young schizophrenic soldiers, most of whom experienced their first psychotic break soon after entering the Army. The aim of the unit was to restore these soldiers to duty and allow them to finish their full Army commitment. It was well known that other treatment methods had been unsuccessful in accomplishing this aim. Patients could stay on these units up to six months.

As described earlier, the Hahnemann modification differs materially in patient population and length of stay but less so in ultimate purpose: the restoration of the patient to his community function. Yet it would appear that the principles of the intensive therapeutic milieu, of the primary role that adequate communication plays in the treatment of not only the schizophrenic but all seriously disturbed patients, has been justified by this much more heterogeneous operation. The geriatric patient, with his infinite variety of functional diagnoses and almost constant overlay of organic factors, appears to be yet another category of patient that can benefit from this modality.

Within such units, active participation by all members of the patient group is expected and demanded. There are no acceptable reasons that would excuse any patient from participation in all of the group activities. It was originally felt by some members of the staff that the geriatric patient would be unwilling to participate in a meaningful way with other patients 50 or 60 years his junior and that the age-related problems were so mutually exclusive as to prevent any interaction. This obviously did not prove to be the case, and there also was no stereotyping of the role of the geriatric patient. Although at times the geriatric patient was protected by the group, this does not appear to have been generally true with the three patients discussed. Hostile interchanges frequently took place, and the staff then used them in appropriate ways to illustrate the patient's dynamics, for example, in the case of a depressed geriatric patient.

The push for active participation would in these cases appear to contradict the disengagement theory of Cumming and Henry (4). Regarding the normal geriatric population they surveyed, the authors felt that the tendency of older people to withdraw from the mainstream of life was a normal part of the aging process. Others, of course, have disagreed strongly with this concept. In our experience at Hahnemann Hospital with a population exhibiting pathological psychological symptoms, it would appear that forced participation within a heterogeneous age group is therapeutically advantageous. A question we cannot answer is whether a similar program with a ho-

mogeneous age group would be equally beneficial.

This question assumes major importance at this point because of the ever-increasing demand that is being made upon medicine in general and psychiatry in particular to participate more actively in the care of the geriatric patient. The tendency to structurally and functionally isolate the geriatric patient into separate services, buildings, etc., is already well established. What is not fully understood at this point, however, is whether this is the best method to control the problem. Controlled studies are desperately needed to resolve this problem prior to the expenditure of large sums of money.

The fear that a geriatric "boarder" engenders in most general medical and psychiatric services is one of the chief obstacles to our providing adequate treatment for these patients. But on a unit with extremely limited facilities, we were able, through aggressive family intervention and social services cooperation, to handle all of the geriatric patients that came onto the unit. In Pennsylvania, as in many other states, the state hospital system is (to put it mildly) loath to accept any geriatric patients. It is, in essence, an avenue that is no longer open to us, and we have had to arrange our own disposition resources. Easy solutions such as building larger and better old age homes, nursing facilities, or state hospital pavilions may not be the best answer.

DISCUSSION

JACOB H. FRIEDMAN, M.D.[1] (Bronx, N.Y.)—Dr. Nathan has the foresight to show that a geriatric patient with functional illness complicating a mild organic brain syndrome can be successfully treated with short-term therapy on the psychiatric ward of a general hospital, among a heterogeneous age group. However, his ward is a 14-bed psychiatric unit with a staff consisting of a Board-certified psychiatrist and graduate psychoanalyst, two first-year residents in psychiatry, a social worker, a part-time psychologist, approximately 14 nurses, an art therapist, and a recreational therapist—a total of 21 professionals, with perhaps additional attendants. I do not know of any ward in a nonprivate mental hospital, especially a state hospital (formerly the "dumping ground" for the geriatric patient), that has the number of qualified psychiatric personnel that Dr. Nathan was able to acquire. Dr. Nathan states that he does not have the answer to whether a similar program with a homogeneous age group would be equally beneficial.

Two published papers from Bronx State Hospital (1, 2) answer Dr. Nathan's question. At Bronx State Hospital, which is affiliated with Albert Einstein College of Medicine, Bronx, N.Y., we have had a new geriatric admission policy (1) since 1967 that excludes patients with nonpsychotic organic brain syndromes, mild psychoses, and mild psychoneuroses; and we have been able to change our original 14 geriatric wards from an inactive custodial unit to an active therapeutic unit (2). On this unit we use individual psychotherapy, group psychotherapy, therapeutic community meetings, small group meetings with selected patients, family therapy, recreational therapy, occupational therapy, work for pay, sensory training and reality orientation, chemotherapy, occasional electroshock therapy, a minor hotel ward, and an active aftercare clinic. We have reduced our geriatric population to a four-ward unit, which eventually will be reduced further to a two-ward unit. Our main difficulty is that often a recovered patient, ready for discharge, has nowhere to go and must be kept for months in the hospital unnecessarily. A geriatric crisis intervention team (3) at Bronx State Hospital has been successful not only in keeping the geriatric patient in the community but also in alleviating his symptomatology, even to the point of recovery.

If further attention were paid to the geriatric patient in outpatient clinics, much hospitalization would be unnecessary. An unusually successful geriatric mental hygiene clinic (4) was established in 1961, the first of its kind in the United States to be connected with a community general hospital, and I was its director. Before this clinic could be initiated, valid reasons (5) for its needs had to be submitted. It was financed through a grant from the New York City Community Mental Health Board and the Board of Trustees of Lebanon Hospital, Bronx, N.Y., which was renewed on an annual basis. Unfortunately, the clinic was discontinued in 1964 for financial reasons, for what were considered more pressing psychiatric problems involving the younger population in the community. A personal communication (6), dated January 28, 1972, from the Biometry Branch, National Institute of Mental Health, states, "To date, there may be only very, very few if any outpatient psychiatric clinics in general hospitals or community mental health centers serving the geriatric population exclusively." The organization of a geriatric mental hygiene clinic can easily be achieved in any community general hospital.

At Bronx State Hospital we have not been successful in mixing geriatric patients with younger patients on one ward. We do not have the sufficient and proper staff that Dr. Nathan has been fortunate in procuring. Dr. Nathan proves that the mentally ill geriatric patient can be helped even in the psychiatric ward of a general hospital, among patients of all ages, provided there is ample help and the proper philosophy.

KARL MURDOCK BOWMAN

Karl Murdock Bowman
1888–1973

KARL MURDOCK BOWMAN, one of the nation's most distinguished psychiatrists and a former President of the American Psychiatric Association, died in San Francisco on March 2, 1973, at the age of 84. He had an especially long and notable career and did not fully retire until 1967, when he was 78 years old; this was 11 years after his retirement to emeritus status at the University of California. He was as active during those retirement years as he had always been: teaching half-time for several years and continuing his research and writing, acting as visiting professor of psychiatry at the Siriraj Medical School in Bangkok, Thailand, and serving from 1964 to 1967 as Director of Mental Health for the State of Alaska and as superintendent of the Alaska Psychiatric Institute at Anchorage. Earlier, at the request of the United States Public Health Service, he had helped to plan the mental hygiene program for the new state.

Dr. Bowman was born in Topeka, Kans. After his graduation from the University of California School of Medicine in 1913, he worked at Bloomingdale Hospital in New York City and the New York Neurological Hospital, and from 1921 to 1936 was chief medical officer at the Boston Psychopathic Hospital, where he worked closely with Macfie Campbell. During those years he taught at the Boston University College of Medicine, Harvard Medical School, Simmons College School of Social Work, and the Smith College School of Social Work. In 1936 he assumed the directorship of the division of psychiatry at Bellevue Hospital in New York City, and during his time there he began the fundamental investigations in the fields of alcoholism and shock therapy that were to interest him for many years. He was professor of psychiatry at the New York University College of Medicine, where he remained until his appointment in 1941 as the first chairman of the newly created department of psychiatry at the University of California School of Medicine in San Francisco and as first medical director of the Langley Porter Clinic (later Neuropsychiatric Institute). His broad vision and indefatigable efforts helped develop the Institute into one of the first-class psychiatric institutions in the country, where teaching and research programs flourished.

In 1935 Dr. Bowman was appointed a Lieutenant Commander in the U.S. Naval Reserve, and in 1952 he was transferred to its honorary retired list. Over the years, he served as a consultant to the Army, Navy, Air Force, Veterans Administration, and U.S. Public Health Service, becoming especially active during World War II. He was a member of the National Research Council's Committee on Neuropsychiatry and a director of California's research into sexual deviation. His love of travel helped him to enjoy his many services to foreign countries, among which were his organization of a psychiatric department at the University of the Philippines and, in 1947, at the invitation of the World Health Organization, the organization of the National Neuropsychiatric Institute at Nanking for the Republic of China. During the war years he served twice as President of APA, and he also served two terms as a director of the American Board of Psychiatry and Neurology. He served on a number of editorial boards, including those of *The American Journal of Psychiatry, Quarterly Journal of Studies on Alcohol, California Medicine, Quarterly Review of Psychiatry and Neurology,* and *Geriatrics.*

Dr. Bowman's research interests ranged widely, most notably into the fields of schizophrenia, alcoholism, geriatrics, and sexual problems. His bibliography lists more than 200 references; one of the last was a report on the major earthquake that struck Alaska while he was at the Alaska Psychiatric Institute in Anchorage. He was a plain speaker whose courageous, frank, and knowledgeable statements on controversial subjects were characteristic of him throughout his long career of academic and public service. Long before civil rights became a watchword, he was outspoken in asserting the rights to legal protection and medical care of the mentally ill, sex offenders, addicts, and alcoholics.

Karl Bowman was honored many times. In 1964 he was the first recipient of the Royer Award for contributions to psychiatry in the San Francisco Bay Area; he received the Wellcome Silver Medal in 1920 for research on psychiatric disorders and their effect on the military; and he was given the Thomas W. Salmon Award in 1968 for distinguished service in psychopathology. He was awarded the honorary degree of Doctor of Science by his alma mater, Washburn College in Topeka, Kans., and of Doctor of Laws by the University of California.

Karl Bowman cared a great deal about a lot of things; what he cared about he worked for and, if necessary, he fought for. He cared deeply about his family and raised four sons—each to carry on a distinguished career of his own. He cared about his students and expended great amounts of thought and energy to improve the quality of their training and to encourage them to grow into humane and sensible physicians. He cared about his colleagues and was always ready to share their problems, encourage their interests, and appreciate their successes. Most of all, he cared about all the patients—his own and others'—for whose benefit he practiced medicine, taught students, ran hospitals, recruited needed professional workers, wrote papers, harangued administrators and legislators, and carried on an incredible variety of activities that filled every day of his life, almost to its end.

Karl Bowman was my mentor and friend, and I appreciated his willingness to give younger people a chance to grow, to mature, and to assume responsibility and authority. He always said he tried to pick good people and thereafter expected them to do a good job. What was unusual was his ability to let them do it their own way and to be tolerant of the diversity of professional viewpoints and activities that inevitably developed. He himself had a broad perspective of the entire field of psychiatry and of the related fields that grew increasingly important throughout the course of his career. While he might become impatient with the overenthusiastic proponents of a particular idea or point of view, he never failed to listen and was always ready to accept as much as he felt had merit.

Dr. Bowman is survived by his widow, the former Anna Lowrey, and three sons—Richard S. Bowman, Ph.D., Thomas E. Bowman, Ph.D., and Walter M. Bowman, M.D.

Erik Erikson has written of the personal integrity achieved by "him who in some way has taken care of things and people and has adapted himself to the triumphs and disappointments adherent to being, ... [who has accepted] his one and only life cycle as something that had to be and that, of necessity, permitted of no substitutions." That was Karl Bowman. He gracefully accepted his share of life's disappointments and deservedly enjoyed a large share of its triumphs. He never failed to take care of the things and people for whom he cared and felt responsible as physician, teacher, colleague, friend, father, and husband. Everyone who was in some way a part of his life will always be glad he was a part of theirs.

ALEXANDER SIMON, M. D.

Lawrence Kolb
1881–1972

Honor a physician with the honor due
unto him,
For the Lord hath created him.
For of the Most High cometh healing.
The skill of the physician shall lift
up his head;
And in the sight of great men he
shall be in admiration.
The Lord hath created medicines out of
the earth;
And he hath given men skill,
That he might be known in his marvellous
works.
Then give place to the physician,
for the Lord hath created him.

—Ecclesiasticus 38

ON NOVEMBER 17, 1972, Lawrence Kolb, the man who perhaps more than any other was responsible for the great advances in mental health in the United States, died at the age of 91.

Born in Galesville, Md., Dr. Kolb received his degree of Doctor of Medicine from the University of Maryland in 1908. Following an internship at the University of Maryland Hospital he was commissioned an Assistant Surgeon in the U.S. Public Health Service in 1909. His graduate work in psychiatry was carried out at the New York Psychiatric Institute, where, more than 30 years later, his son Dr. Lawrence C. Kolb was to serve as director.

In 1910, Dr. Kolb married Lillian Hess Coleman of Baltimore, Md.; they had three children: Dr. Lawrence C. of New York City, Charles of Raleigh, N.C., and Mrs. Otis A. Shorr of Cincinnati, Ohio.

Dr. Kolb's early career in the Public Health Service afforded him wide experience in psychiatry and mental health that was ideal preparation for heading the Mental Hygiene Division. From 1919 to 1923 he served as medical officer in charge of the Hospital for Nervous Diseases at Waukesha, Wis., where he pioneered in providing psychiatric care for veterans of World War I. From 1923 to 1928 he was assigned to the Hygienic Laboratory in Washington, D.C., the precursor of the National Institutes of Health. During these years Dr. Kolb was occupied with investigations of drug addiction, and his studies were largely instrumental in providing the basic psychological and biological information concerning the phenomena associated with this condition; his publications remain classics in the field.

His interest in drug abuse and alcoholism persisted throughout his career. From early in his career he was outspoken in his opinion that they are illnesses, in spite of the powerful opposition that expressed the popular attitude of the day that the basic etiologic factor was deliberate criminal behavior. Dr. Kolb publicly asserted that, in his opinion, government control was incapable of solving the problems of addiction, which he believed was rooted in deep-seated psychopathology. Time has proven his courageous position to be correct. He not only was among the first psychiatrists to recognize the value of Alcoholics Anonymous but he also early pushed for a similar type of organization for drug addicts. His interest in the subject persisted until his late life and found fruition in the publication of his last book, written when he was 82.

From 1928 to 1933 Dr. Kolb was in Europe carrying out studies related to the problems encountered in the mental examination of foreign nationals seeking to emigrate to the United States. These studies were important in the revamping of the examining instruments and criteria for admission to this country. In 1933 he was given charge of the Department of Justice medical center, then under construction in Springfield, Mo. Under his direction this hospital launched its trailblazing endeavors in the treatment and rehabilitation of mentally and physically ill offenders.

In 1934 his expertise in the field of narcotic addiction made Dr. Kolb the logical choice to open and direct the federal government's first major facility for treating the addict. He was designated medical officer in charge of the first U.S. Narcotic Farm (as it was called), which was then under construction at Lexington, Ky. The world-renowned research program at that institution was conceived and brought into being by him.

In 1938, Dr. Kolb became Chief of the Mental Hygiene Division of the U.S. Public Health Service, the predecessor of the National Institute of Mental Health. He remained in that position until his retirement in 1944. During that time he was instrumental in launching such innovative programs as the psychiatric treatment centers for merchant seamen, the mental health screening program at the Coast Guard Academy, and public health training for mental health personnel. His administration

spanned the major portion of the trying World War II years. Dr. Kolb was promoted to the rank of Assistant Surgeon General in 1942.

Following retirement from the Public Health Service, Dr. Kolb became medical consultant to the California State Department of Corrections and, later, Deputy Director of the California State Department of Mental Hygiene. He retired from this position in 1951 and went to Norristown (Pa.) State Hospital as assistant superintendent; at the same time he served as secretary of the Philadelphia Mental Health Survey Committee until he retired to writing and consultation in 1954, at the age of 73. In 1965 he was awarded the Salmon Medal by the New York Academy of Medicine for his contributions to psychiatry and mental health.

A recital of the career of this remarkable man cannot communicate the warmly human side of his character or his vision, leadership, keen insight, and dedication to improving the lot of the mentally ill. Quietly forceful, he was an excellent organizer and administrator who inspired not only loyalty and respect but deep affection in his subordinates. He watched over and brought to professional maturity most of the career psychiatrists in the U.S. Public Health Service who occupied key positions during the early days of the national mental health program. While he was Chief of the Mental Hygiene Division he blazed the trail that made possible passage of the National Mental Health Act some years later.

There would be no national mental health program as we know it today had it not been for his pioneering efforts. Unfortunately, the time was not ripe for Dr. Kolb's concepts to be translated into legislation. His proposal for a National Neuropsychiatric Institution was endorsed by the American Psychiatric Association and the National Committee for Mental Hygiene, but other potent organizations lacked his vision and withheld their endorsement. Congress was not ready for a truly comprehensive national mental health program, but World War II taught the American people some bitter lessons about the human and financial cost of mental illness. The result was that, building on Dr. Kolb's ideas and the ground he had broken, those who followed him were able to accomplish what he had dreamed of and labored so hard for.

This man, who planted trees in whose shade he knew he would never sit, who played his seminal role quietly yet effectively, will always stand as a model for those who would aspire to leadership not only in psychiatry but in any field of human endeavor.

ROBERT H. FELIX, M.D.

Psychiatrists in the Ghetto

SIR: I appreciated Dr. William M. Bolman's detailed and forthright articles about "Community Control of the Community Mental Health Center" (August 1972 issue), but his very directness raised serious questions for me. Consider this: "It has been estimated that the mortality rate of ghetto community mental health center directors is close to 90 percent within a two- or three-year period. . . . Many, like myself, go back to teaching to lick their wounds and describe how it happened." Why did Dr. Bolman go back to teaching after only 18 months? That's not a very long time—hardly enough to know if you married the right person, probably an average time for psychotherapy to really get started, probably enough time to discover that a relationship is unworkable. Would a doctor interested in setting broken bones have this kind of trouble in the ghetto? Probably not. Why does the mental health movement seem to be having so much trouble? Maybe it is because it has nothing to offer the ghetto.

I have a naïve belief that people will in some way appreciate what you do *for them*. If they are not appreciating it, I wonder if it is for *them*. Does the ghetto need or want to learn what the mental health movement has to teach?

Dr. Bolman talks of the problems mental health professionals meet in the ghetto: the challenge to professional control, the intensity of community involvement, the difficulty in changing to new service settings and approaches. Would a competent reading teacher resent a challenge to his professional control? Would he resist intensity of involvement on the part of his students? Would he have any trouble teaching in different settings? No, he would encourage challenge, intensity, and change because they all represent student involvement, which is the heart of learning. As far as I am aware, all that is required for learning and teaching is the presence of two active minds.

But if the teacher has an uncertain focus, if he is unsure of his subject matter and of his relationship to his students, then he will worry about challenges to his control and about variability of setting. I think this is the position of psychiatry in the ghetto.

To quote Dr. Bolman again: "Irrationality tends to flourish in such a setting, and the usual work pleasure from experiencing a good job well done simply vanishes. In its place, and for extended periods of time, comes whatever joyless satisfaction derives from survival in a tough job that needs doing." Does such a joyless job really need doing?

I have a simple answer to why Dr. Bolman left after 18 months—the people in the ghetto didn't want to learn what he had to teach, and it took him that long to realize it.

PETER A. ROEMER, M.D.
Silver Spring, Md.

Dr. Bolman Replies

SIR: Dr. Roemer raises several valid questions that my articles apparently didn't clarify. Although he offers his own answers, I'm grateful for the opportunity to say how things looked to me. First, why did I go back to teaching after 18 months? Because I took Harry Truman's advice on politics: "If you can't stand the heat, get out of the kitchen!" I found that I simply couldn't stand the heat. In other words, it became clear that the range of activities and skills required, the painfully limited resources relative to need, the intensity of the struggles, the hours required, etc., were beyond my ability to manage. It might be of interest to note that in my own case, at least, the conflicts with the community could be worked out much more productively than the conflicts with the various medical and psychiatric elements (e.g., private practitioners, the medical society, the hospitals). I believe these conflicts existed because the medical elements did not generally wish to change the existing structure unless this was done on their terms; hence they perceived me as a threat or aggravation and tended not to cooperate. The community, on the other hand, had nothing to lose and hence saw me as perhaps being helpful and worth a trial.

Second, Dr. Roemer asks: "Would a doctor interested in setting broken bones have this kind of trouble in the ghetto?" The experience of those who have tried (1) says that the answer is yes. If that doctor needs to make a living (ghetto dwellers can't afford private practice fees), or believes he is a gift to the ghetto, or has trouble relating to the poor, to blacks, etc., he'll have lots of trouble! More basically, however, the problem is not so much that of individual doctors, but rather, of the absence of a rational delivery system.

Third, Dr. Roemer wonders if the ghetto needs or wants what the mental health movement has to teach. I wonder too. Most mental health teachings and practices are so oriented toward middle-class white-values that they don't have much use in this setting (2). Further, a good case could be made for the proposal that the ghetto doesn't need psychiatrists, but it needs a revitalization of the Bill of Rights—jobs, opportunity, housing, safe streets, relief from oppression. Or, to say it differently, it needs political and societal cures, not psychiatric cures. However, if you rephrase the question to read: "Do people in the ghetto need, desire, and appropriately use mental health services?" the answer is an unqualified yes!

Fourth, would a competent reading teacher resent a challenge to his professional control, etc.? Dr. Roemer says: "No, he would encourage challenge, intensity, and change because they all represent student involvement, which is the heart of learning." If so, psychiatry has lots to learn from reading teachers, because I know a lot of psychiatrists who *don't* encourage challenge, intensity, change, and involvement! I entirely agree with the other part of his point, that mental health has ridden so madly in all directions that now we're quite lost. Re-sorting, reevaluating, and choosing priorities, roles, and functions out of the 1960s mental health explosion (largely due to the Community Mental Health Centers Act) will be a major challenge to the profession. I only hope that psychiatry is sufficiently up to the challenge to play a role in some of the decisions.

Concomitant Imipramine and Methylphenidate Administration: A Case Report

SIR: Perel and associates (1) and Wharton and associates (2) described the elevation of plasma imipramine (Tōfranil) levels when methylphenidate (Ritalin) was administered concomitantly.

We would like to describe here our experience with one patient who received high-dosage levels of imipramine and showed marked clinical improvement when methylphenidate was added to his treatment schedule.

> J.B., age 61, had a 19-year history of depressive disorder. Many treatment modalities had been attempted with little success, and he had been hospitalized continuously for the prior three years. Treatment with 300 mg. of imipramine a day resulted in some improvement, but he still required hospitalization. Within four weeks of adding methylphenidate (final dosage, 40 mg.) to the treatment schedule he showed marked improvement. Upon withdrawal of methylphenidate he rapidly returned to his previous state.

Imipramine and desmethylimipramine levels were determined on plasma collected four hours after the morning dose of medication. The method used was that described by Harris and associates (3) with some modifications. The samples were collected during baseline, at eight weeks (imipramine only), and then when methylphenidate was added (20 mg., later 40 mg.) and subsequently withdrawn.

The plasma levels showed a marked increase in both the imipramine and the desmethylimipramine when the patient received methylphenidate: baseline imipramine, 30 ± 20 ng./ml.; desmethylimipramine, 200 ± 10 ng./ml. (four measures each). Later, methylphenidate plasma levels rose rapidly and steadily to a peak value of 575 ng./ml. and 300 ng./ml. of imipramine and desmethylimipramine, respectively. Within two weeks after the methylphenidate was withdrawn, the plasma levels had returned to the baseline values. The marked clinical improvement followed the same time course as the elevation of the plasma levels. This confirms the observation of Perel and associates (1).

Residential Treatment: Should It Be Concomitant with Family Therapy?

SIR: I must take strong exception to Dr. Paul M. Fine's statement that residential treatment "is a court of last resort for any system of family or child psychiatry" in his review of Kahan's book *Mental Illness in Childhood: A Study of Residential Treatment* (February 1973 issue).

Indeed, intensive residential treatment with concomitant family therapy is, rather, the treatment of choice for borderline and psychotic children and adolescents whose psychopathology in effect expresses profound failure of separation-individuation, in turn engendered by similarly profound parental and familial psychopathology (1–3). Very often the best and best intentioned therapeutic efforts are foredoomed if these youngsters are left with their pathogenic families. By the same token, unfortunately, many prestigious private and public residential facilities for youngsters operate with conceptually muddled programs that ultimately prove to be incapable of coming to grips with the enormity of the patients' and their families' essentially autistic nexus of relationships. It is basically for these reasons that seriously ill youngsters continue to receive short shrift from both outpatient and inpatient facilities purportedly devoted to treating and to curing them.

Finally, I wish to know what Professor Fine means by "system of family or child psychiatry," particularly since he refers to residential treatment as a court of last resort for it, whatever the latter phrase may mean.

DONALD B. RINSLEY, M.D.
Topeka, Kans.

Dr. Fine Replies

SIR: I believe that Dr. Rinsley and I are essentially in agreement, falsely polarized, perhaps, by a literary allusion. By a "court of last resort" I did not mean to imply that residential treatment is, or should be, the last resort for individual patients for whom residential treatment is indicated. The court of last resort was meant to allude to a therapeutic setting designed well enough to "do justice" to even the most difficult cases. Too often these patients are shunted into programs that are ill equipped to deal with them. By a "system of family and child psychiatry" I hoped to convey the idea of competent services coordinated to meet a broad spectrum of needs and therapeutic indications, including prevention, casework, case finding, outpatient treatments, day hospitals, residential treatment, rehabilitation programs, and follow-up.

Intensive residential treatment centers, as Dr. Rinsley correctly points out, are in some cases the only setting that can do justice to a variety of difficult situations. The fact that they exist also strengthens work in other less intensive settings throughout the entire system of care. Dr. Kahan's book seemed significant since it contained some practical guides toward setting up that most scarce of clinical resources—an intensive residential treatment center for preadolescent children.

Statements About Viet Nam: APA's Role

SIR: What an intellectual pleasure to read the Letter to the Editor of Dr. Virgil M. Cox, Jr. (January 1973 issue). I wonder why so many righteous leaders in our specialty were so upset in

1972, when from 1962 through 1968 they seemed to be cheerfully developing community mental health programs while the Kennedy and Johnson administrations shipped hundreds of thousands of young men to Viet Nam. How come they are so overwhelmed and horrified in the 70s? Did they have to wait for a change in administration?

It pains me to hear a professor of a postgraduate course at Columbia University making fun of our President and implying that the people of this land are "sick" because they voted for Mr. Nixon. I believe that if we "educated people" don't show respect for our government, then what do we expect our children to respect? They, the "unenlightened ones," are inviting disaster, and I am afraid I shall be a witness to it.

Quoting Dr. Cox, "I wonder how everyone else feels?"

HECTOR CORRAL, M.D.
Long Branch, N.J.

SIR: I am in complete agreement with the ideas expressed in Dr. Cox's letter, in which he expressed his dismay at the statements made about Viet Nam by some of our members in business and scientific sessions at the annual meeting.

I, too, am disturbed at the idea of our association being used by some members as a platform for the expression of extreme left-wing liberal political ideology. I am convinced that in the long run such behavior will not only harm the image of psychiatry as a whole, but will also be detrimental to the credibility of APA.

In conclusion, let me state that in my opinion psychiatrists as professionals cannot fairly claim to have more expertise or insight into political issues than responsible members of other professions. Therefore, I do not feel that APA as an organization should write position statements on the conflict in Southeast Asia or on the solution of other political issues. I am strongly convinced, however, that it is the duty of each individual psychiatrist, whether he be liberal or conservative in his political convictions, to seek to influence government decisions by writing to senators, congressmen, etc., and by expressing these convictions when suitable opportunities occur.

WALTER C. JOHNSON, M.D.
Hanover, Mass.

Succinylcholine in EST

SIR: About 20 years ago my associates and I published one of the first papers on the use of succinylcholine in electroshock therapy (1). Since that time, there appears to have been relatively little advance in electroshock therapy.

For years we have noticed that some patients who make little, if any, response to shock treatment (curative response) often experience an incomplete seizure. The seizure is either brief in duration, is partial, or ends abruptly. Occasionally, a patient may not have a seizure at all. If a large amount of succinylcholine is used, the psychiatrist might not even be aware of a deficient seizure. Seven or eight years ago we started giving intravenous pentylenetetrazol (Metrazol) to enhance the seizure in these patients.

The average patient is given 8 cc. of a ten-percent solution of sodium methohexital (Brevital). The needle is left in the vein and the syringe is removed. Twenty to 80 mg. of succinylcholine, depending on the patient, is then administered. Again the needle is left in place and the syringe removed. Five to 8 cc. of pentylenetetrazol is promptly administered intravenously.

After a wait of approximately one and a half minutes, during which time the patient is given positive-pressure oxygen, treatment is then given. The average dose of pentylenetetrazol is 5 cc., but we are not hesitant to increase this dosage if indicated. The pentylenetetrazol does not arouse patients, and they receive excellent treatments. We have seen neither delayed seizures nor status epilepticus. By using succinylcholine the seizure is little more pronounced than in an ordinary successfully administered electroshock treatment.

I believe that it is well known that intravenous diazepam (Valium) is probably the best medication to use in terminating status epilepticus. Occasionally one will encounter a patient who, while recovering from the administration of an electric treatment, becomes highly disturbed. This is similar to the state of a patient in the first stage of anesthesia. It occurs whether or not a patient has had pentylenetetrazol. We have found that the administration of 1 to 2 cc. (5 mg. per cc.) of diazepam intravenously is a superb quieting agent. In such cases the diazepam is given immediately after the effects of succinylcholine have worn off. Intravenous diazepam tends to depress respiration, and for this reason, patients should be kept in the treatment room until respiration is well established.

Often the same dosage of diazepam seems to prevent, or minimize, posttreatment headaches.

I am writing this letter in the hope that others may find our experience helpful.

Sexual Freedom in Adolescents: A Reaction Formation?

SIR: One questions whether the so-called sexual freedom of adolescence is really what it appears to be. In conjunction with this sexual freedom there is also a freedom of homosexual behavior. This exposes the adolescent during the developmental stage of seeking a heterosexual identity to all of the literature written by confirmed homosexual adults.

With the echoes of an earlier homosexual developmental stage still reverberating, could this sexual freedom be a reaction formation to the anxiety created? Could this be a "driven" behavior or a protest against homosexual stirrings rather than a healthy heterosexual adaptation?

I have observed several adolescents assume a homosexual identity on the basis of reading literature by confirmed homosexuals without ever giving themselves a relaxed heterosexual experience for comparison.

Many of these young people do not know that latent homosexual responses (or active homosexual behavior) do not preclude a rewarding, mature heterosexual adaptation.

Alton, Ill.

Danger of Depot Phenothiazine Treatment in Acute Psychosis

SIR: In their article "Depot Phenothiazine Treatment in Acute Psychosis: A Sequential Comparative Study" (January 1973 issue) Drs. Chien and Cole advocate the use of depot phenothiazine in the treatment of acute psychosis. At the

present time I have a hospitalized patient who was treated this way at another hospital. The patient currently has a white blood count and differential of 5,000 WBC, 3 STABS, 16 SEGS, 74 lymphocytes, 3 monocytes, and 4 eosinophils.

Perhaps it would be more prudent and safer to be concerned about the development of serious hypersensitive reactions and to allow patients a three-week trial on an oral form of the drug before starting on an intramuscular route. It seems to me that hypersensitive reactions to almost any substance can develop and that to start with an irretrievable, oil-suspension, intramuscular injection is not using the basic logic of pharmacology.

JOHN B. SCHOONMAKER, M.D.
Syracuse, N.Y.

Drs. Chien and Cole Reply

SIR: Dr. Schoonmaker describes a patient with borderline leukopenia, apparently without other symptoms, who had received fluphenazine enanthate. He then questions whether it is ever wise to start patients on a long-acting injectable phenothiazine without a prior trial on an oral form of the same drug.

His position is logical, cautious, and conservative. All we can say by way of rebuttal is that neither we nor the manufacturers of the long-acting injectable drug are aware of any instances of toxicity or hypersensitivity that are clearly attributable to the drug. Two case reports of hyperthermia in patients who had received the enanthate have been reported, but the patient in the case most recently reported (1) ended up being maintained on the enanthate without further toxicity. Dr. Schoonmaker's case report would not deter us from giving the drug as an initial therapy if we felt the clinical situation warranted it. The drug form is useful on an acute service and is uniquely valuable in crisis intervention in the home or in the emergency room to prevent the psychiatric hospitalization of psychotic patients.

Dependence in Man: A Psychoanalytic Study, *by Henri Parens, M.D., and Leon J. Saul, M.D. New York, International Universities Press, 1971, 251 pp. $10.*

Dependence has come to have a pejorative connotation in psychiatric practice. When it is discovered in our patients, it is a defect to be exorcised. The authors' contribution is to treat dependence as a normal human condition with its own epigenesis. "When we speak of dependence we mean the need each human has, whether child, adolescent, or adult, for a libidinal object relation in order to ensure his optimal psychic functioning."

The first part of this book reviews Freud's writing on childhood, with its lengthy period of helplessness and dependence. These are then related to the early prototypical danger situations that produce anxiety: 1) fear of loss of the symbiotic object that gratifies dependency needs and 2) fear of loss of the object's love that follows the libidinal object tie, which in turn motivates identifications leading to instinctual repression and promoting the formation of psychic structure. Freud postulated that "the libido attaches itself to the satisfaction of the great vital needs, and chooses as its first objects the people who have a share in that process." This serves as the basis for the second part of the book, which deals with theoretical considerations. Here the authors differentiate this view from that of the British analysts (Balint, Fairbairn, Guntrip, Bowlby) and the ethologists who argue for primary object attachment in the newborn human (and, by implication, from the theories of Robert Sears, who considers dependency a primary motivating force in the newborn).

The authors cogently discriminate between two groups of animal species: those whose neonates are altricial and those with precocial neonates. Animals in the first group, including the human, are born with an immature nervous system with less capacity to perceive, to execute motor acts, and "also, the less operative those potential instinctual structures that subserve the development of object relations." Here the authors follow Spitz, Anna Freud, M. Schur, and most child psychoanalysts, who hold that a level of perceptual and emotional motivation and differentiation—a psychological organization or intrapsychic structure—is a prerequisite for object relations. According to this view the maximum intensity of psychologic dependence (an emergence of clinging behavior in response to separation anxiety) appears just after six months of age, when the object acquires specificity for the child and the process of separation-individuation begins. The more altricial the organism, the more will dependence become a factor in early life experience and the more will maternal care be required for survival.

In contrast are those species (e.g., geese, ducks) whose neonates are precocial, born in a state of central nervous system maturation that allows for a significant degree of cognitive, affective, and motor functioning. In these species, unlike the human infant, there is neonatal imprinting, with rapidly secured object attachment. Experimentally, the neonate can attach to an out-of-species object.

Using a "developmental line" model based on the work of Anna Freud, Mahler, and Erikson, the authors formulate in chapter 5 "an epigenesis of psychologic dependence" from birth to late adulthood. They find it useful to divide libidinal needs of each stage into two components: affectional and sensual. "Affectional" refers to the necessary psychic nutriment derived from object relations: emotional support, protection, and care. Brief clinical examples in the final chapter illustrate dependence as a defense as well as defenses against dependency needs.

The style of the book is uneven. The various sections of the book form different styles and paces as if the two authors put together separate essays. Even so, this is a useful book, placing dependence as an independent variable in human development. It is a contribution to both theory and practice.

ROBERT D. GILLMAN, M.D.
Washington, D.C.

Sigmund Freud and Lou Andreas-Salomé: Letters, *edited by Ernst Pfeiffer. New York, Harcourt Brace Jovanovich, 1972, 242 pp., $7.95.*

In 1911 Lou Andreas-Salomé, at the age of 50, attended the Psycho-Analytical Congress in Weimar and was captivated by Freud and psychoanalysis. A year later, a correspondence that was to last a quarter of a century began with a letter from Lou Andreas-Salomé to Freud expressing her delight that he had responded favorably to her request to come to study with him in Vienna. Her interest in psychoanalysis was the culmination of a search begun in her teens to find a way to synthesize passion and intellect, mind and body, faith and love.

The sensitive, introspective only daughter of a religious Russian general of German Huguenot origin, she had in her early teens turned away from life to a world of fantasy. In an attempt to find her way back through spiritual understanding, she sought at the age of 16 instruction in religion, art, and philosophy from a pastor in her native St. Petersburg. Following her disenchantment when this man of God, 25 years her senior, proposed marriage to her, she became ill.

At the age of 20 she journeyed to Rome to recuperate and there began her contacts with many of the great writers and intellectual personalities of her time. She traveled widely and numbered among her friends persons like Tolstoy, Strindberg, Rodin, and Schnitzler. She was particularly close to Nietzsche and Rilke. The impact she made, the experience she had, and the impression she left varied. Some men admired her and were friendly. Others admired and adored her and were her lovers, and still others admired, loved, and were hurt by her. At 26 she married F.C. Andreas, a noted philologist who became a professor at the University of Göttingen. Their marriage lasted 50 years but was not a sexual union.

Lou Andreas-Salomé had achieved a reputation as a novelist and essayist when, at the age of 50, she undertook the formal study of psychoanalysis. She considered this move a turning point in her life and thought of Freud as the father figure who presided over her life. She remained in Vienna for approximately one year and then returned to Göttingen where she practiced psychoanalysis and from whence most of the letters were written. She rarely left Göttingen, and her contact with Freud was maintained largely through mail.

Much of the correspondence deals with interchanges about her reactions to Freud's writings. Although she was most respectful of what he had to say, she did not always agree with him. While he emphasized analysis and attention to detail and logic, she tended to make broad generalizations and attempted

syntheses that Freud often considered premature. He admired her perceptiveness and poetic insight into such subjects as narcissism, sublimation, religion, and masochism, but at times he gently chided her for the lack of clarity in her arguments and for making assumptions not warranted by the available data.

These letters contain much more than an exchange about theoretical ideas. There are references to many of the important figures in psychoanalysis and insight into the substantive issues as well as the personality clashes that influenced the development of psychoanalysis and its ramifications. Their letters express their concern for each other's welfare and the welfare of their families during a historical period of great anxiety and deprivation. They share their pleasure in the achievements of Freud's daughter Anna, who had become Lou's good friend. Freud responded to Lou's request for advice about problems she encountered in the course of her work with her analysands. Freud was cheered by her optimistic outlook, which contrasted with his own pessimism not only about his failing health but the future of mankind.

At the present time, when Freud's concepts of female psychology are being so widely discussed and challenged, this book affords an interesting insight into the complexity of Freud's attitude toward women. He was obviously attracted to this beautiful woman whose experiences had been so intriguing, and he was also pleased by her admiration, almost adoration, of him. To what extent these factors motivated his encouragement of her career in psychoanalysis is hard to determine, for it is also clear that he admired her intelligence, which sometimes baffled him. He referred to her intelligence as "exquisitely feminine" in its efforts to "tidy everything up." While at times his responses to her speculative and obscure theorizing were patronizing, he also wrote of her "superiority over all of us in accordance with the heights from which you descended to us." Never did he demean or disparage her, but rather he encouraged her to continue to work and explore her thoughts.

REBECCA Z. SOLOMON, M.D.
Hartford, Conn.

Urban Challenges to Psychiatry, *edited by Lawrence C. Kolb, M.D., Viola W. Bernard, M.D., and Bruce P. Dohrenwend, Ph.D. Boston, Little, Brown and Co., 1969, 496 pp., $15.*

This work sums up what 14 members of the faculty of the Department of Psychiatry of Columbia University College of Physicians and Surgeons in New York learned from the community and from each other during more than a decade of mutual experience in developing psychiatric services for 100,000 people packed into a small geographic area of Manhattan.

As should be hoped of a service program developed by a university medical center, throughout the project the group held before itself high standards of objectivity and documentation as it set about learning, recording, scrutinizing its results, and relearning how to provide effective psychiatric services in a model district of urban core life.

The contributing authors approach this challenge from several disciplines and varied perspectives as clinicians, administrators, and researchers. The red thread giving this work its particular identity through time and multiple viewpoints is Lawrence C. Kolb, who opens the volume with a chapter on "The Concept of the Community Mental Health Center" and closes it with a chapter on "Search and Research." Professor Kolb also shores up the middle of the line with chapter 8 on "Medical and Psychiatric Services" and chapter 10 on "Failure in Bureaucratic Organization and Hope from Local Action," as well as having a share in other contributions to the book.

Counterpoint to the chapters on the evolution of clinical concepts and programs starts with chapter 3, "A Social History of Washington Heights to 1960." It provides the background for a number of chapters by sociologist Bruce P. Dohrenwend, who, along with others, describes the development of their attempts to answer the big question: "What effect did all these programs have on the people in Washington Heights?" The reader will not find the much-sought-after answer to that question by turning to the last chapter, but he will find a very realistic and sophisticated statement of the current state of the art in Professor Dohrenwend's chapter 19, "The Challenge in Retrospect and Prospect: A Research-Oriented View."

While the knights of community psychiatry do not present us with the Holy Grail in this work, they have a great deal to tell us of what they have learned, their mishaps and adventures, in the quest. Some of this will not be interesting to everyone, but all of it should be fascinating to some. Is your academic department thinking of running a health program for the public? Read chapter 13 on "Urban Psychiatry—Effects on the Psychiatric Institute: Some Comments on the Dynamics of Institutional Change" by Alvin M. Mesnikoff. Or maybe your mental health center serves a population that does not believe in mental illness. In Washington Heights not many people did either, but what is fascinating is that community leaders, regardless of their politics, were well aware that some of their constituents had mental abnormalities and needed treatment.

Clinical points, as well, received scrutiny. Continuity of care is a principle applauded in all branches of medicine. Yet as the principle was applied in the Washington Heights study, it led, beyond dispute, to marked increases in the duration of psychiatric hospitalization.

Repeatedly throughout this work it is evident that research on program quality and program effectiveness was frustrated by the impact of mental health systems outside the Washington Heights area on the lives and illnesses of the study group within the area. We are all quite familiar with the complexity of the variables, the many social institutions and forces that influence people's behavior and that are beyond the scope of psychiatric treatment systems. What this work makes vividly clear is that as patients over a period of time passed through a variety of municipal and state treatment systems other than those of the study district, often for quite arbitrary reasons, the quality of care provided by each of these systems probably deteriorated, and certainly nobody knew what was going on.

The psychiatric services provided in Washington Heights, and their evaluation, are not the only pattern for urban mental health programs, or necessarily the best, but we must be grateful for the high-caliber documentation and the thoroughness and objectivity of the research that have been provided in this unique communication. It is an achievement for a comprehensive mental health program to survive in an urban core, without the additional burden carried by these authors of documenting, studying, and reporting on their experiences every inch of the way.

Prisoners of Psychiatry: Mental Patients, Psychiatrists and the Law, *by Bruce Ennis. New York, Harcourt Brace Jovanovich, 1972, 232 pp., $6.95.*

Bruce Ennis is uniquely qualified to write about the injustices

of certain forms of involuntary psychiatric hospitalization. For the past four years he has served as director of the Civil Liberties and Mental Illness Litigation Project of the New York Civil Liberties Union, and he has devoted his full time to test case litigation on behalf of mental patients. In this book he not only acknowledges the help of many dedicated, if not heroic, psychiatrists in the difficult, truly landmark cases he has struggled with, but (unusual in a work of this type) he clearly identifies, perhaps unwittingly, the reasons for our bankrupt system of involuntary institutionalization and makes constructive proposals for correcting it. Our laws and their administration, not psychiatry or psychiatrists, are attacked with vigor and logic.

The introduction, written by the well-known anti-psychiatry psychiatrist Thomas S. Szasz, detracts from the quality and value of the book. Szasz exhales fire and thunder and lashes out his usual stinging denunciation of his colleagues, this time singling out (the reader can theorize why) the revered Karl Menninger as "one of the staunchest and most influential psychiatric supporters of involuntary mental hospitalization." Naturally, mental illness is still a metaphor and a myth and mental hygiene laws should not be updated but repealed.

Like Szasz, the author has a naïve, if not cavalier, view of major mental disorders. But his epilogue, in which he highlights the shoddy thinking that underlies the inappropriate and harmful handling of large numbers of mentally ill patients, is provocative, and because it is reasoned and in good taste, it deserves serious consideration by psychiatric and legal scholars. It is refreshing to read not the nihilistic, destructive "solutions" of Szasz, but concrete and, I believe, workable recommendations.

Long-range reform proposals include limiting the application of the "danger" standard for commitment to persons who have recently committed or threatened substantial physical injury to themselves or to others (this has already been adopted in several states, most recently New York State); requiring hospitals to show that they provide something more than the same food, clothing, shelter, and structured environment one finds in a prison; and abolishing patient labor or requiring hospitals to pay fair value for that labor. The author outlines short-range reform measures, most notably the mandatory assignment of counsel and a mandatory judicial hearing (unless affirmatively waived by the patient after consultation with his counsel) either before or promptly after hospitalization.

I have the feeling that Mr. Ennis would be astonished to know that his views are far more likely to be favorably received and supported by the leadership and membership of the American Psychiatric Association than by their counterparts in the legal profession.

If one can disregard the irrelevant, demagogic, sophistic, anti-psychiatric diatribe in Dr. Szasz's nine-page introduction, the book should be considered must reading by lawyers and mental health professionals alike. Retitling it *Prisoners of Judiciary—Mental Patients, Judges, Lawyers, and the Law* would facilitate its acceptability in this regard. The book should be published in paperback so that it can be read widely by laymen as well.

Port Chester, N.Y.

Society Pays: The High Costs of Minimal Brain Damage in America, *by Camilla Anderson, M.D. New York, Walker and Co., 1972, 228 pp., $6.95.*

The title of this book clearly conveys the author's thesis: that minimal brain damage (or dysfunction) is an extremely common disorder which is largely responsible for a wide variety of psychiatric and social pathologies. Dr. Anderson first states that the minimal brain damage (MBD) syndrome, produced by either neurological noxae or a genetic phenocopy, is responsible for an appreciable fraction of the behavioral pathology and cognitive difficulties of childhood. Available data would suggest that approximately five to ten percent of latency age children do indeed suffer from a mélange of overlapping signs including overactivity, coordination deficits, impulsivity and social immaturity, and a variety of perceptual and cognitive deficits variously labeled according to their severity and patterning as hyperactivity, minimal brain dysfunction, perceptual-motor problems, specific learning disabilities, and dyslexia.

Whether this diverse group of psychological signs forms a true syndrome or whether, like retardation, it represents the lumping together of etiologically and phenomenologically discrete subgroups is currently a matter of investigation. Evidence does exist that such behavioral abnormalities can occur on the basis of true neurological injury or fetal maldevelopment, and that they probably can be produced by genetic factors and possibly by deviant psychosocial experience. That the entire syndrome occurs on the basis of brain damage is unlikely, and the meaningfulness of grouping these children together is problematical. The author believes that it is useful to so cluster these individuals, and she includes in the syndrome—as most researchers working in the field would not—an indefinite subsample of Bleuler's group of schizophrenias. She thus broadens the concept of MBD to an extent not generally employed by other workers in the field.

Her second major assertion—again supported not by hard data but by her clinical hunches—is that the syndrome is not outgrown in childhood but persists into adult life, where its manifestations become protean. She believes that MBD "matures" into psychosis, sociopathy, "inadequacy," and a multitude of hitherto undesignated psychiatric nonspecificities. Documentation for such an assertion could consist of evidence that a disproportionately large number of persons falling into these diagnostic categories had manifested typical signs of MBD in childhood or that follow-up studies of children with MBD revealed that such outcomes constituted part of the natural history of the disorder. Such documentation is not provided.

The above summarizes the author's two major theses. They are advanced on the basis of her clinical experience alone, and she provides none of the evidence necessary to support her extreme position. With regard to the etiology of such MBD problems in childhood, the role of neurological factors is unclear. One of the major concerns of the multimillion-dollar perinatal study of the National Institute of Neurological Diseases and Stroke is to evaluate the role of biological factors in the production of such abnormalities in childhood. The role of genetic factors, too, remains unclear. Clinical experience may suggest that the disorder runs in families, but the perennial problem of interpreting such findings is in separating the roles of genetic and experiential factors.

The methodological strategy necessary for this purpose is that of adoption studies. Such studies have been employed in the schizophrenias and are beginning to be explored in the affective disorders, sociopathy, alcoholism, and MBD itself. With the exception of the schizophrenias, studies of these disorders have not been completed, so that the role of genetic factors in their etiology still remains unproved. However, two recent adoption studies of MBD are consonant with a genetic hypothesis. In regard to follow-up studies of children with MBD and retrospective analyses of adult sociopaths and psychiatric nonspecificities, there is some literature that would bolster Dr. Anderson's opinion, but she does not cite it.

Relatively recent follow-up studies have shown that children with MBD run a higher risk of schizophrenia (Robins, Menkes) and sociopathy (Robins, Mendelson, and Stewart). Retrospective data suggest that there is a childhood history of MBD-like behavior among impulsive adolescents (Hartocollis, Quitkin, and Klein) and that children with MBD are grossly overrepresented among high school underachievers (Hammar). It may very well be that in many instances MBD is a chronic disorder and one not limited to childhood, but the data currently available are suggestive, not conclusive. In an effort to substantiate her beliefs, the author calls upon a potpourri of ambiguous circumstantial evidence whose major effect, unfortunately from her standpoint, is not to strengthen her argument but to lay open to question the validity of her clinical judgment. Her attempt to document her position with such fragmentary data is unfortunate because her book may contain an extremely useful clinical hunch or, as it is more fashionably called these days, a hypothesis-generating thesis.

In summary, Dr. Anderson has made some rather sweeping assertions on the basis of clinical experience rather than hard data. There may be a very large element of truth in what she says, but her attempts to substantiate her beliefs are unsuccessful. This weakness, together with her outspoken assertions that psychosocial *krankheiten* are the products of biological deficits rather than social and psychological oppression—a view contrasting sharply with the prevalent mood of social, not biological, meliorism derived from Locke—will combine to make this book one that is rejected out of hand and not read. This will be unfortunate because it is quite likely that the author does have some useful clinical hunches, and it will be unfortunate if the baby—however small—is thrown out with the bath water.

Compensation in Psychiatric Disability and Rehabilitation, *edited by Jack J. Leedy, M.D. Springfield, Ill., Charles C Thomas, 1971, 348 pp., $15.*

This excellent book by several authors from many disciplines should be a reference volume for all of us who must deal with this perplexing and difficult problem. It crystallizes the fact that there must be a meeting of minds among psychiatric, psychologic, sociologic, legal, insurance, and rehabilitation interests so that the primary goal of rehabilitation to the fullest possible degree (including, it is hoped, return to a job) can be realized—and not crucified on the cross of special interests and vague and inconsistent psychiatric and legal definitions. Compensation should not be the primary goal. There should be early referral to a psychiatrist following any injury or incident on the job—especially when nothing organic can be found, but also because the attending physician should always be aware of the possibility of attendant emotional and personality factors.

My many years in private and industrial practice and involvement with national and state rehabilitation councils and agencies and with insurance companies have impressed on me these points:

1. Rehabilitation must be a written policy in any workmen's compensation program, to begin on a certain day following the injury or incident. Tough steps must be taken to check on the R aspect (rehabilitation) in the progress of the case to be sure that the patient receives total rehabilitation—physical, psychiatric, psychologic, family counseling, retraining for a job, etc.

2. Insurance companies have complained that psychiatric referrals are not made early or often enough to be effective in early detection and treatment of psychiatric complications.

3. Education of all medical and paramedical personnel involved in the case should be continuous regarding the possibility of emotional and personality complications, and they should refer their suspicions to the medical person in charge.

4. Vocational rehabilitation agencies should be involved early. Because the late Mary E. Switzer had the foresight to establish psychiatric training programs for rehabilitation counselors, these agencies can be very helpful in the restoration process of psychiatric patients.

The following chapters are especially worth reading: "Economic Factors in Psychiatric Treatment and Rehabilitation" by Talkington, "Differentiating Compensation Factors from Traumatic Factors" by Ross, "Occupational Risk Factors in Mental Health and the Impact of Role Change Experience" by Trice and Roman, "Compensation for Psychiatric Disorders" by Brill, and "Rehabilitation—A Key to Adequate Recovery in Personal Injury Cases" by Broder. The insurance carriers' viewpoints concerning reemployment and new employment of the mentally restored following an employment injury or incident would have been helpful. In view of General Motor's Carter case (1), Norman Brill's statement is reassuring: "The flood of cases feared as a result of the precedent set by the Carter case apparently has not occurred." This decision could have been a difficult obstacle in influencing employers to hire the mentally restored.

Hilton Head Island, S.C.

The Neuroses: A Psychoanalytic Survey, *by P. C. Kuiper, M.D., Ph.D. New York, International Universities Press, 1972, 251 pp., $9.*

This is the English translation of a textbook for students of psychoanalytic psychology by a Dutch psychoanalyst and clinical psychiatrist who has been a visiting professor at the Menninger Foundation.

It is much more concise than Fenichel's *The Psychoanalytic Theory of Neurosis* (1) and it may prove to be a useful successor to that book at least until the rumored revision of that text has been produced. Although Kuiper's book includes less detail than Fenichel's, it presents relatively more clinical orientation in comparison with the theoretical elaborations in Fenichel's accounts of neuroses.

In his introductory and theoretical chapters Kuiper emphasizes that nosological and dynamic-genetic considerations are *both* valuable and not mutually exclusive. In his chapters on the various neuroses and neurotic character disorders he relates his psychoanalytic discussions to the clinical entities of European psychiatry, which have again been accepted in the official American nomenclature (2). For example, he includes various types of hysterical neuroses and hysterical personality and also neurasthenic, depersonalization, and hypochondriacal neuroses. He also includes a Kretschmerian "sensitive personality" but fails to mention some of the other personality disorders that are in the American nomenclature and that might be considered to be related more to the psychoses than to the neuroses.

In my opinion the author is rather sparing in his account of depressive neuroses and seems not to recognize a possible relationship between neurasthenia and depression. He is skimpy in

details about traumatic neurosis, although he does make the important distinction between the sequelae to traumatic anxiety and the conditions associated with secondary gain, which he calls "pension neurosis." The sections on hysterical neuroses, in which he differentiates between these disorders in males and in females, and the section on obsessive-compulsive neurosis include more enlightening detail.

The main shortcoming of this translation, published in 1972, is that there are no references to the literature subsequent to 1962. The book would be vastly improved as a modern psychoanalytic textbook if it included ideas from such theoreticians in psychopathology as Arlow, Balint, Brenner, Nagera, Nemiah, Kohut, Sandler, and Winnicott, to name only a few.

Nevertheless, this book can be highly recommended as a textbook for beginning students of psychoanalysis, who should be trying to relate their dynamic-genetic formulations to clinical psychiatric diagnostic classifications.

Annual Progress in Child Psychiatry and Child Development: 1972, *edited by Stella Chess, M.D., and Alexander Thomas, M.D. New York, Brunner/Mazel, 1972, 732 pp., $15.*

The appearance of the fifth volume in this series prompts a look at the selective process and the quality of the papers included and also suggests a concern about the need for such an annual review. It is apparent that not only in this volume but over the years, Chess and Thomas have put together collections that are both catholic and of high caliber.

The papers included in this volume, as well as those in the earlier issues, range from articles concerned with special research topics to more specifically clinical and treatment papers. A survey of the material selected over the five-year period illustrates quite clearly changes of interest in various topics. The research areas covered concern infancy, various developmental issues, perception and learning, and specific concerns about handicapping conditions. It is obvious that there has been a great shift from articles concerned with pure treatment phenomena to a major interest in learning and developmental problems.

The articles in the present volume are indeed good. It was a pleasure to see Lester Mann's article on "Perceptual Training Revisited: The Training of Nothing at All." It was equally reassuring to read once more Barbara Fish's article on the "Myth of Stimulants in Hyperkinesis" as well as the more classical Eisenberg paper on "Principles of Drug Therapy in Child Psychiatry." Jane Knitzer's critique of advocacy represents a most important viewpoint on this currently spotlighted topic. The editors can also be commended for including Ritvo's article on "Social Class Factors in Autism." There does seem to be a contradiction between Birch's report on "Functional Effects of Fetal Malnutrition" and Schultz and Aurbach's somewhat different point of view in their article on "Usefulness of Cumulative Deprivation as an Explanation of Educational Deficiencies."

Having said that these are good articles and that the rest of the papers are of comparable quality—do we need such an annual review? All the material comes from readily available journals. The compilation suggests only minimal bias on the part of the editors. Certainly there is no attempt to present a digest that would downgrade the quality of the original papers. The collection is handy, but it could be prepared as easily and more cheaply by any reprint-minded individual.

The pattern of such review books is well established. Undoubtedly there will continue to be publications of this nature. Undoubtedly they will be helpful to librarians and individuals who lack access to a wide range of article materials. To those whose tastes range more widely, they may be a partial boon but perhaps an unnecessary one. There is, no doubt, solace in the minds of the authors in seeing their papers thus reprinted, but the collection of articles into a review volume can be questioned both in concept and in practice.

No doubt there are many advocates of this method of reviewing the literature. It is possible, however, that a more appropriate mechanism needs to be discovered. Science fiction continually suggests that we are on the verge of having readily available print-outs to scan on complex video machines. Science may be ready to provide us with these now, but cost keeps us locked into the printed page. Of these printed pages, there does seem to be a superfluity at all times. Perhaps our goal should be to avoid some of the repetition and redundancy in our publications.

Summary Report of the Special Policy Meeting of the Board of Trustees, Atlanta, Ga., February 1–3, 1973

Summary Report of the Special Policy Meeting of the Board of Trustees, Atlanta, Ga., February 1–3, 1973

THE PURPOSE OF the Special Policy Meeting was to consider ways and means of improving the policy planning function of the APA Board of Trustees. Although this function has long been recognized as the primary function of the Trustees, the pressures and complexities of acting on the ever-expanding amount of routine APA business in recent years has tended to erode it. How to clear more time to allow the Board to carry out its policy planning function was the focus of the agenda, which was developed by a subcommittee consisting of Drs. Melvin Sabshin, chairman, James Johnson, and Robert Gibson.

More specifically, the Trustees brought with them a common sense of the need to reassess the ever-changing structure of APA, the dynamics of the relationships among components that it has engendered, and the implications of these for coping effectively in developing policy and programs. For example, there are the matters of the maturation of the Assembly of District Branches in recent years and its telling role in formulating policy; of the growing importance of the Reference Committee of the Board; of the fundamental impact of the Committee on Constitution and By-Laws; and of the relatively new phenomenon of multiple slates of candidates for office, which dictates that some will be elected who have not previously been notably involved in APA affairs or who have not been part of the evolutionary process that has led to the current structure. The Trustees also brought a deep concern over the rampant criticisms that attend psychiatry today (both from without and within) and how best to deal with them.

This was the fourth Trustees' meeting of this kind. The first, known as the Airlie House Conference, was held in 1964, the second in 1968, and the third in 1971. Reports coming out of all of these meetings were published in the *Journal*.

Broadly speaking, the first day of the meeting was devoted to problems of internal organization and the second day to external policy issues and relationships. The meeting opened with a series of formal presentations followed by discussion. The meeting then broke into small group workshops where specific recommendations might be formulated and presented to a final plenary session for action.

INTERNAL AFFAIRS

The Role of the Trustees vis-à-vis Other Components

Dr. Ewald Busse, immediate Past President, made a number of major points in his presentation:

- The Reference Committee and the Committee on Constitution and By-Laws, both of which are relatively small and composed primarily of appointed individuals, have become increasingly influential in policy formation and in determining APA priorities.
- The unwieldy size of the Assembly limits its ability to act promptly on matters of immediate concern.
- The efficiency of the Board of Trustees fluctuates depending on the traits of its current members, the kind of material (medical, social, political, etc.) that is under consideration, and the type of decision-making process that is being utilized.
- APA is recognized professionally and legally as an educational-scientific organization composed of psychiatrists. It has five stated objectives. Therefore, all policies and procedures should be directly relevant to these objectives and to the structure of APA. We must keep this principle foremost in our minds, for if we do, it will expedite and clarify the decision-making processes of the trustees.
- Dr. Busse reviewed the constitutional status and definition of the Board of Trustees (established in 1969), its Executive Committee, the Reference Committee, and the councils, committees, boards, and other entities. He took particular note of the change in the structure of APA since 1964. In 1964, there were six constitutional committees and three standing committees, as opposed to eight constitutional committees now. Currently, APA has eight councils, 40 task forces, 21 committees, four commissions, and 15 boards and other organizational entities (a total of 88), as compared respectively with three coordinating committees, 30 committees, 15 boards, commissions, and special committees, four ad hoc committees, and seven sections (a total of 59) in 1964.
- The amount of responsibility assigned to each of the eight councils must, of course, vary, but there is a tendency to be extreme in this regard. Currently, for example, one council is responsible for a single task force, another for 18. This matter should be under constant review by the Reference Committee.
- It is worth noting that the Committee on Constitution and By-Laws consists of six members, two appointed each year for a three-year term. One reappointment for an additional three years may be made at the discretion of the President, who also designates the chairman.
- The Assembly of District Branches has several functions: 1) to represent and serve the needs of the branches, 2) to discuss any matter brought to its attention, 3) to recommend policy to the Trustees, and 4) to submit referenda to the voting membership. The Assembly's procedural code describes it as the "legislative component" of APA; however, this is not so stated in the Constitution and By-Laws.
- Dr. Busse ventured the opinion that several principles postulated by Mr. Charles L. Schultz, Director of the Bureau of the Budget under President Johnson, were applicable to APA's various decision-making processes. Among them were

that political and social dimensions are so complex that it is unwise to make radical changes or to implement long-range plans that are difficult to deviate from. Movement toward objectives should proceed by *small* sequential steps that allow for correction and adjustment as we move along. For example, very carefully controlled pilot studies should determine the evolution of medical services, and no pilot study should be permitted to continue for longer than seven years, at which time it must be totally evaluated and the whole program reinitiated.

As Schultz also pointed out, endless hours are wasted on political policy decision making because discussants do not separate relevant from irrelevant ideas, facts are lacking or badly presented, the relationship of the policy under discussion to other projects and policies is not spelled out, conflicts in values are not identified, and possible alternatives are not adequately considered. All must be included in sensible policy decision making. The longer range the policy, the more the alternatives must be considered.

Operations of the Assembly of District Branches as They Pertain to the Trustees

Dr. James Johnson, Speaker of the Assembly, made a number of major points in his presentation.

- The Assembly of District Branches started out in a kind of organizational vacuum from which its present role gradually evolved. One early problem was that the original state associations, which were converted into district branches, originally harbored physician members other than psychiatrists. Accordingly, the district branch as a legal entity had to be separated from the state association as such. This divided organizational arrangement still persists in some states.
- The branches serve as a forum for discussion of common problems at the local level; these problems are often brought to the national level through the area council, where they are debated and resolutions often formulated for consideration by the Assembly. The very structure of the Assembly makes it useful as a means of information exchange among members. The Speaker, Speaker-Elect, and Recorder tend to serve as moderators more than leaders, and they attempt to secure compromise in impasse situations. About 145 APA members are involved in the Assembly (delegates, alternates, area representatives, and area alternates).
- In the early stages of development, communication was tenuous between the Assembly and the Reference Committee and almost nonexistent with the Board of Trustees. The Assembly functioned largely unto itself with relation to the branches. Its own committees and task forces were established on an ad hoc basis and bore little relation to parallel committees and task forces under the Reference Committee.
- About a decade ago it was decided that all new members would enter the Association only through the district branch route. As a result, the Assembly began to take on two new roles: 1) the initiation of policy recommendations, and 2) the restraint of independent policy decision making by the Trustees and the Reference Committee. It passed resolutions for Board approval or disapproval. This process was often tedious. It could, and sometimes did, take as long as three years for a policy decision to be finalized, and the final product often bore no relationship to the original intent. At this point the Speaker of the Assembly was appointed to the Reference Committee to speed up the process, but this was not entirely successful. Often the information at his disposal was not sufficiently developed, or the Assembly, because of time limitations, had not adequately considered matters referred to it by the Reference Committee.
- There is currently the need and desire to improve communication between the Trustees and the Assembly. A method has been found by which the Assembly may communicate matters of concern directly to the Reference Committee, thus circumventing the former routing to the Board and then back to the Reference Committee. The increased responsibilities delegated to the staff in generating possible positions on social issues and legal matters are also helpful. The Assembly and the Reference Committee are now primary instruments in policy development.
- Both the Assembly and the Council on Internal Organization have Committees on Public Information. However, these committees are mostly concerned with organizational affairs and do not generate very much information for the public on what is relevant and important in the field.
- In general, while the mechanisms for studying issues have greatly improved, largely through the Assembly's referral process to area councils, there is still room for improvement.
- The Assembly is moving toward a quasi-legislative role in APA affairs. It has a viable mechanism for implementing action through its area councils and district branches. Currently it is especially heavily involved with such vital matters as recruiting young members and establishing a nationwide system for peer review and a system for continuing education.

APA Staff Operations as They Pertain to the Trustees

Dr. Walter Barton, Medical Director, presented this topic under the following headings:

The Assembly of District Branches. Dr. Henry Work, Chief of Professional Services, provides staff support for the Assembly. He is assisted by Ms. Ann Whinnie. The work involves preparing minutes, implementing the communications process, planning and organizing meetings, formulating agendas, developing backup materials, and following through on implementing Assembly actions and resolutions.

The Trustees and the Executive Committee. In recent years the staff has assumed many administrative tasks that were formerly reserved for decision by the Trustees. These tasks are currently considered routine operations within established policy. The staff maintains elaborate cross-indexed files on policy decisions and has published a digest of policy statements. Working with the Secretary, the Medical Director prepares agendas for meetings and provides backup materials for information, clarification, and presentation of options in the decision-making process. This is a critical function since failure to have such information at hand means postponing the problem for further study and often entails wasted time spent in discussing a matter that cannot be resolved without further information. The staff also assists the Secretary in developing minutes of the meetings and in following up on actions and policies to ensure their implementation.

Reference Committee and councils. The Medical Director and the Deputy Medical Director perform the same functions for the Reference Committee as for the Board of Trustees. Dr. Donald W. Hammersley, Deputy Medical Director, coordinates the activities of the eight councils under the Reference Committee. The staff often identify a problem (frequently suggested by members) and forward it to the appropriate council for consideration. Telephone conferences among councilors and staff are authorized to expedite matters requiring quick action. Dr. Hammersley is assisted in his work by other key staff members to whom the councils are assigned for servicing, i.e., Dr. Work (Council on Medical Education, Council on Research and Development), Dr. Mackey (Council on National Affairs), Dr. Barton (Council on Internal Organization), Mr. Robinson (Council on International Affairs, Council on Emerging Issues), and Dr. Hammersley (Council on Professions and Associations, Council on Mental Health Services). As the councils' work ex-

pands, they require more staff support in processing manuscripts, follow-up actions, and facilitating communications with all parties concerned.

Special problems currently facing the Trustees are: 1) What to do with resolutions received from the Assembly that do not clearly indicate what action is to be taken if and when they are approved and published; 2) liberating time from routine matters to use for policy considerations (the Trustees cannot sit as an "editorial board" in reviewing a large number of manuscripts, for example); and 3) keeping current with the mission and progress of all important matters under study by all components.

Role of staff in policy formation. Inevitably the staff must play a key role in developing APA's response to federal legislative issues. This role is a matter of broadly interpreting established APA policies to apply to a given situation. Usually, this is done through consideration by an intrastaff policy group. It may be that the establishment of a judicial council or possibly more frequent meetings of the Executive Committee of the Board could, in some measure, ameliorate staff responsibility in this important area.

Replacement of the Medical Director. The importance of the immediate appointment of a Search Committee to find a successor to the Medical Director was emphasized.

Expectations of Airlie House: How Far Have We Come?

Dr. Henry Brosin presented this topic for Dr. Robert Garber.

• Generally implicit in the Airlie House deliberations was the conviction that we must evolve an APA that reflects a balance between stability and flexibility. To achieve such a balanced mechanism we above all need a truly effective data collection and disseminating system that touches all components. *Psychiatric News* has made a great contribution, but it is not enough. We need speedy feedback mechanisms between the processes of data input and processing through the central office to the various components concerned. The critical importance of this is sharpened by appreciating the many destructive forces impinging on us (e.g., the loss of federal support for needed manpower, the attacks on the medical profession in general, the supposition that untrained people can treat the mentally ill, and the widespread criticisms of the profession). It is indeed a time for alarm.

• At Airlie House the Trustees (then called councilors) were overwhelmed by the "staggering complex of organizational components" in APA that were operating without coordination toward a common purpose, that had overlapping functions, and that did not have sufficient autonomy or authority to get things done; this resulted in a waste of energy, money, and time. The Trustees made clear their primary concern with policy and their inability to focus on it because of their involvement with administrative routine. They resolved to drastically change the Trustee-committee structure into a council-task-force-oriented structure in order to overcome these basic flaws.

• After several years' experience, however, we cannot state with confidence that the Board of Trustees is functioning up to the level of the Airlie House expectations. There are too few "thinking" or "policy-making sessions" and too many "debating," "dissecting," or "quarterbacking" sessions on the content of reports that the Reference Committee has already carefully sifted. Moreover, reports from task forces, councils, and committees still get buried and lost, chiefly through the back-and-forth referral process among the components involved. In sum, many of the pre-Airlie-House problems still remain with us.

• Recommendations were made: 1) that the chairmen and members of the eight councils be "ruthless" in discharging unproductive task forces and in guaranteeing against duplication of effort among them; 2) that they insist on the rapid conversion of all task forces into truly project-oriented groups to accomplish specified goals in a reasonable period of time; 3) that the councils process reports more quickly; 4) that the confidence originally invested in the Reference Committee's function be reaffirmed; and 5) that renewed determination be manifested to implement the Airlie House proposition that the Trustees discharge their constitutional responsibility and desist from excessive involvement in administrative detail. There has indeed been progress since Airlie House but by no means enough.

EXTERNAL AFFAIRS

What Are the Boundaries of Psychiatry? What Is a Psychiatrist?

This topic was presented by Dr. Hayden Donahue, who made a number of salient points.

• The evolution of psychiatry can be traced back at least 2,000 years, although the term "psychiatrist" did not come into use until the 1830s. Most would now agree that psychiatry is the medical specialty that deals with the study, treatment, and rehabilitation of the mentally ill and that it is both an art and a science.

• There is, perhaps, no consensus about a definition of mental illness, although many definitions have been offered over the years. A recent effort by Dr. Ewald Busse suggests the following definition:

> A mental illness is an altered physiologic and/or anatomic state of the nervous system, manifested by maladaptive signs and symptoms including emotional and thought disturbances and/or alterations in behavior that prevent the individual from functioning in a manner acceptable to himself or to others. The biological change is sufficiently fixed or refractory that it does not spontaneously subside or favorably respond to alterations in the usual life experiences.

This, and comparable efforts at definition, deserve careful consideration. It is not enough simply to define mental illness as any disorder officially described in the second edition of our *Diagnostic and Statistical Manual of Mental Disorders (DSM-II).*

• There is even less consensus about a definition of "mental health," and there is widespread doubt that the term can be properly defined. This has handicapped the profession in many subtle ways. For example, the World Health Organization defines health as a "state of complete physical, mental and social well-being." Clearly, no human being can qualify as a healthy person under such a definition. To accept it literally is to lead psychiatry far afield from the medical model, which, indeed, has already happened to an uncomfortable degree. The problem is compounded by the fact that the etiology of the mental illnesses is so complexly rooted in physiology, psychology, and the environment.

• Other disciplines, especially psychology, social work, and nursing, share several qualities of psychiatry, and the contributions of all the behavioral sciences have long since become recognized as essential to advances in the field. But these disciplines neither share *all* of the qualities of psychiatry, nor is any as uniquely positioned as psychiatry in clinically applying them to mental illness. Beyond his medical assets per se the psychiatrist brings to the treatment of his patients certain knowledge, skills, and attitudes stemming from his professional train-

ing that may be categorized as follows:

Responsibility. This is inculcated into the physician as a student, intern, and resident. It can never be relinquished, and it is not equaled in any other profession. It results from a long tradition; it is a model on which each physician finds a base for identity and behavior.

Psychodynamics. The trained psychiatrist understands the crucial influence of the irrational in human affairs; he listens with a "third ear." He is aware of the importance of separating conscious from unconscious motivational processes. He knows that they must be handled differently. The basic principles of human psychology apply to all interpersonal relationships, albeit many skeptics tend to deny the relevance of psychodynamics as behavioral determinants in persons who are not labeled patients.

Growth and development. The discovery of handicaps or disabilities is only one of the problems approached by the psychiatrist who is concerned with prevention, correction, and adjustment. The helping task may consist of helping many patients to accept incomplete growth rather than in trying to change an existing situation. Because of his theoretical and clinical knowledge concerning standard, "normal" phases of growth and development in the human organism and of the changing interaction of individuals and forces in the environment, he is competent to differentiate between arrested development and regression. The professional, having a cultivated sense of the longitudinal life-span, is alert to the possibilities for awakening and challenging latent growth potentials.

Interpersonal process. The well-trained psychiatrist has a sense of timing and process in interpersonal relationships, that is: 1) an awareness that a relationship proceeds through sequential phases of development, and 2) knowledge of how to guide that development—to shift responses and to influence techniques adaptively—as the quality of the relationship changes with changing circumstances over time.

Professional objectivity. The psychiatrist comprehends the difference between empathy and sympathy. His trained ability to keep his emotional vulnerabilities relatively separate from the disabilities and misfortunes of his patients is usually an asset. The professional helper's ultimate purpose is to lead and to guide the patient to a point of self-sufficiency that makes the helper no longer needed. Ideally, then, the help given has an educational or maturational component and, at carefully determined times, delaying or withholding help is the most constructive move possible.

Interviewing technique. Professional interviewing includes more than friendly conversation, information gathering, or even establishing rapport. It involves both diagnostic and therapeutic dimensions. Inexpert interviewing, particularly in the initial stages of an assistance relationship, can create serious obstacles to subsequent communication.

Countertransference. The mental health professional, through instruction and supervision, has acquired experience with countertransference phenomena and knowledge of how to recognize them and of how to get help, if needed, in using and controlling them. In short, he wears special eyeglasses for looking at both members in an interchange—himself as the professional as well as the patient. He has learned that the source of misunderstanding, misinterpretation, and skewed communication may reside in either or in both.

The clinical psychologist, the social worker, and the nurse all acquire many of these qualities. The properly trained psychiatrist, however, with his background of medical discipline and psychoanalytically oriented psychology, is the most likely to achieve a full range and depth of all of these skills.

- In general, psychiatry as a medical specialty must take stock of its positive assets. We must define our field of competence and leave those areas in which we have neither training nor competence to others who have. We must base our science on solid research. We must clarify our concept of mental illnesses and improve our definition and classification of them. We must evaluate the many criticisms leveled at us and seek to correct those which are valid and which lend themselves to correction. We must limit our pronouncements to our field of competence and, above all, we should eschew pathological self-criticism.

Consumer Influence on Psychiatry

This topic was presented by Dr. Alfred Freedman, who made the following major points:

- It was not so long ago that it was considered a misfortune when a sick person did not receive medical attention. Now it is generally considered an injustice. Health care is currently viewed as a right, and along with this change in opinion a powerful movement has evolved that seeks consumer participation in the delivery of health services. In mental health services, particularly, the consumer constituency is very broad and is having more and more of an impact. For example, in various federal and state health planning boards it is common to require that more than 50 percent of the board be made up of consumers (patients, relatives, friends, potential users, concerned citizens, etc.). It is in such ways that consumers become active participants in decision making.
- Some highly articulate individuals, both within and outside of the profession, are sometimes perceived as "champions" or "the voice" of the consumer (e.g., Ralph Nader, R.D. Laing, and Bruce Ennis). This creates a serious problem for psychiatry, which has no constituency to respond in its behalf. Moreover, while our critics disseminate all kinds of distortions and half-truths about psychiatry, they often do present penetrating facts that cannot be gainsaid. Our response must not be one of denial, defensiveness, or apology but, rather, one of earnest self-criticism and scrutiny and should result in the development of a positive program to cope with the problems of the mentally ill in our society.
- A related and growing public demand is for various kinds of "bills of rights" that impinge on our field. One thinks of Karl Pribram's demand for a "Biological Bill of Rights," of Morris Chafetz' proposal for "A Bill of Rights for Alcoholic People," of a comparable manifesto of the recently formed Mental Patients' Liberation Project, and of another by the Committee on Health Care for the Disadvantaged of the American Hospital Association. Whatever the special merits of these various declarations, they collectively reflect an overriding concern for patients and their welfare; this is a concern with which APA must closely identify itself. It is time to ask ourselves: Have we, the psychiatrists of America, really made a maximal effort to bring adequate psychiatric care to the poor, to adolescents, to the elderly, to addicts, to alcoholics, to the retarded, and to minority groups?
- The real problem in our country is the lack of meaningful, comprehensive services in places that need them. If we are to become concerned with the consumer, organized psychiatry is going to be faced more and more with the dilemma of where to place its support, on which side, and in what way. With regard to many of the issues that are now emerging, we will have to decide whether we will join with consumer groups or consumer advocates and whether we will be neutral or will oppose them, since very often the targets of criticism are members of our own profession or are institutions in which our members are on the staff. Two occurrences during the past year are illustrative.

One of the most important was a New York State Supreme

Court ruling that a mental patient at Bellevue Hospital in New York City had the right to refuse electroshock treatment that had been prescribed by the hospital's physicians. The court decision pointed out that the law did not specify whose consent was required. In this case the patient refused while her mother consented. The judge wrote the following about ECT:

> This form of treatment is the subject of great controversy within the psychiatric profession, both as to its efficacy and as to its dangers. It has been known to aid significantly in the cure of the mentally ill, as well as to cause such other ailments as pulmonary edema, bone fractures and, in exceedingly rare instances, even death.

The ruling stated that the independent psychiatrists authorized by the court to examine the patient concluded that the 31-year-old woman suffered from schizophrenia but "has the mental competence to consent or withhold consent for her treatment."

The other case was brought by civil liberties lawyer Bruce Ennis in a federal court for $38,500 in damages on behalf of a former mental patient who had been confined in a state hospital for 15 years without significant treatment. Punitive and compensatory damages were assessed against two doctors, the superintendent, and a staff psychiatrist of a Florida state hospital. Mr. Ennis clearly stated that his goal is the abolition of involuntary hospitalization, and he encourages patients to sue for lack of treatment or for illegal hospitalization.

- These are the realities of the ambience in which we are and will be practicing. We cannot be passive or indifferent any longer. What can we do? I believe we can join with consumer groups through the excellence, innovativeness, and accessibility of our programs. Only in this way can the public be educated about what we really do. This area and that of public relations, I believe, are of the utmost importance. We have to think in terms of affirmative, positive action so as to develop a constituency. In the days of Clifford Beers we had a constituency. I do not feel we have one at the present time.
- One must emphasize and reemphasize the central importance of providing accessible, available, and comprehensive programs of undoubted excellence. One must strive to be innovative and to modify treatment programs in accordance with careful evaluation. We must all be convinced, as I am, that psychiatrists must play a central role in the delivery of mental health services, or the public will be deprived of first-rate programs. In spite of the swing of the pendulum, the role of psychiatrists will be increasingly recognized as time goes on.
- It is not the consumers who are the biggest threat to organized psychiatry. The threat, rather, is the dehumanized, systems-analysis-oriented bureaucrats who have little sensitivity to the organization and provision of meaningful mental health services. We should join with the consumer movement in full confidence of the competence of the psychiatric profession.

External Controls and Constraints

This topic was presented by Dr. Robert Gibson, who made the following major points:

- A host of management specialists and governmental technocrats assert that the health care crisis results from a lack of organization in the delivery system and charge that doctors are more a part of the problem than the solution.
- Psychiatrists and other physicians approach the health care crisis with quite different premises. We contend that as professionals we place the good of mankind above personal interests, that we have acquired a vast amount of expertise with which to address the crisis, that we conduct ourselves according to standards of competence which we have set, and that we assume responsibility for policing ourselves. Shall ever the twain meet? Both are sincere. The communications gap must be overcome.
- Clearly, if national health care is to be reorganized, it must be managed—that is, planned, coordinated, staffed, implemented, motivated, and controlled. The concept and its complexity boggles the mind, but all of these elements of management are already very much upon us.

First, there are the professional standards-setting organizations—the Joint Commission on Accreditation of Hospitals, residency accreditation, peer review organizations, medical licensing boards, the American Board of Psychiatry and Neurology, APA itself, and other national medical associations. Participation is voluntary, but failure to "go along" is perilous.

Second, there are the health regulating agencies. Among these we find regional and mental health planning agencies; comprehensive community mental health center programs; state, county, and community boards of health; state boards to license facilities; departments that administer mental health programs; and even drug abuse administrations. It is noteworthy that while the Nixon Administration has stated its intention to give the ax to community mental health centers, it is upgrading comprehensive health planning groups. The comprehensive health planning groups are seeking authority to mandate the services they consider are needed and the facilities in which to offer these services. They are also seeking authority to certify health maintenance organizations, outpatient facilities, and even group practice. If they can regulate group practice through health insurance funding mechanisms, then for all practical purposes the individual private practitioner will fall under their control.

Third, there is a small group of miscellaneous regulating agencies and legislation outside the health field that impinge on the management process—e.g., civil rights groups, the judiciary, welfare agencies, the Fair Labor Standards Act, the Occupational Safety and Health Act, and others. Quite possibly the day is near when an adolescent will be able to challenge in court his parents' decision that he have psychiatric care.

Fourth, there is management through financial control—that is, through private insurance, Medicare, Medicaid, wage-price commissions, private foundations, the National Institute of Mental Health, national health insurance, the Internal Revenue Service, cost review agencies, and others. Some national health insurance proposals proclaim their intention to use funding mechanisms to reshape the health care system. Inherent in these financial control mechanisms is the premise that someone must determine what is adequate and needed health care and what it is worth in dollars and cents.

Finally, there is management by consumers. In this category we encompass mental health advisory committees, unions, individual and class-action suits in the courts, and a range of community action groups. These instruments of management can subserve useful coordination, support, and review functions. But a lack of clarity about their functions can lead to a destructive result.

- All too few psychiatrists are aware of the many diverse ways in which our professional activities are being controlled and regulated. Even fewer are involved in shaping the growth of the management process, and the time grows late.
- There is much, I submit, that we can do, chiefly through APA. For one thing, a proposal has been made to amend APA's Constitution to render continuing education a requirement for membership. The amendment will be voted on next year. APA would set the standards for such education. This is good.

APA district branches can and should ensure that state medical societies identify them as the specialty section in the peer-review systems that the state medical societies are supposed to implement.

APA can participate in the development of controls. Already it is a partner in the Accreditation Council of the Joint Council for the Accreditation of Hospitals, and it must intensify its involvement and strengthen its impact in other control agencies.

APA can and should play a far more telling advisory role based on its expertise. In Maryland, for example, the regional planning agency has designated the APA district branch as a technical review committee; every proposal containing a psychiatric input is submitted to that committee for review and recommendation. This is as it should be.

APA can greatly step up its advocacy role to exert a much greater force on legislation and on the formulation of regulations to implement it, which is often more significant than the legislation itself.

APA can and should expand its public education programs. It has done much, but the fact remains that in a single column Ann Landers can have more impact on the future of health care than years of work by APA.

- In general, we plead that, collectively, the profession must stop reacting reflexively by simply protesting and demanding its prerogatives. It won't work any longer. We must study what is actually happening and must vastly improve our input and feedback mechanisms—as among APA's governing and staff components, for example. We must find a way of communicating with those who view us as more "a part of the problem than the solution." We cannot reverse the trend toward greater management and control, but we can do much to shape its form. To do this, however, we need an overall strategy for responding and for taking the initiative at every possible level. Most of all we must find a way to mobilize 20,000 members behind this mighty effort.

The Need for a New Joint Commission on Mental Illness and Health (JCMIH)

This presentation was made by APA President, Dr. Perry Talkington, who made the following major points:

- Nearly 12 years have elapsed since the publication of *Action for Mental Health*, the final report of the first JCMIH, which was established by the 1955 Mental Health Study Act. Following in its wake, President Kennedy delivered his stirring Special Message on Mental Illness and Retardation in 1963 and this, in turn, led to the Community Mental Health Centers Act of 1963.
- It is time now for a second JCMIH. Psychiatry and psychiatrists have changed drastically in the past decade. The patients have changed, and the delivery and financing of mental health services have changed. We need to find out in a comprehensive way where we have been, where we are now, and where we should go from here. The specific functions and goals of such a joint commission call for careful study and planning. But among its primary concerns should be problems in the delivery and financing of mental health services for all citizens and the manpower problem.
- If we are agreed in principle with the need for a new JCMIH, then, clearly, its elaboration and materialization must be given careful study and projection by some designated group. How shall it be financed? (It will be considerably more expensive than the first commission, which was financed almost entirely by Congress.) What range of organizations shall be encompassed under the term "joint"? Should it be projected exclusively as an APA commission to ensure that the psychiatric point of view is not lost in a forest of many other points of view, many of them denigratory of psychiatry? These and related problems are crucial.

FINAL SESSIONS OF THE MEETING

After the formal presentations (each of which was followed by considerable discussion), the Trustees divided into four working groups, each being asked to consider one of four topics and to report back to the final plenary session with recommendations for specific action. The actions taken by the Trustees under each heading follow.

Topic: Boundaries of Psychiatry

The Trustees referred to the Reference Committee a suggestion that a task force be appointed to define the terms "mental illness" and "psychiatrist."

Also referred to the Reference Committee was a recommendation that the Council on Research and Development assume responsibility for the revision of *DSM-II* and that the task be completed within two years. The trustees recognized that *DSM-II* occupies a unique position in that it is widely used in other countries, as well as in our own. However, in spite of this it was felt that the needs of the profession in the United States should take priority over international considerations. It was also agreed that *DSM-III* should relate the official classification to the problem-oriented-record-system approach. It was also noted that the existing Task Force on Nomenclature and Statistics is currently at work in developing a revised *International Classification of Diseases* (*ICD-9*), of which psychiatry is an important part. If a new task force is to be appointed, it will be important for it to develop close working ties with the current one.

The Trustees recommended that whatever classification is ultimately adopted should contain provision for designating the *degree* of functional disability that accompanies a diagnostic category. The intent is to express functional disability in percentages. It was also held that the term "mental illness" should be defined and used in the context that the absence of mental illness does not necessarily imply the presence of mental health.

Topic: Consumer Influence on Psychiatry

The Trustees requested the current Task Force on Collaboration of the Psychiatrist and the Consumer to study the feasibility of establishing a consumer advisory council and an office of consumer advocacy in APA headquarters. The staff was asked to make a similar study with reference to the mode of functioning and cost of such an office. Both groups were asked to report back in May 1973.

The Trustees referred to the Assembly of District Branches a recommendation that it encourage the branches to function as consumer advocates in their areas and to develop working relationships with various consumer advocate groups.

The staff (Division of Public Affairs), with the help of an advisory committee, was asked to prepare a pamphlet on the general topic of the mentally ill and the mentally retarded consumer. In making the recommendation the Trustees expressed their conviction that patients' rights represented the very essence of their commitment to patients. It is hoped that such a statement from APA might have impact in the states on legislation to safeguard patients' rights.

Topic: External Controls

The APA Budget Committee was asked to find ways and

means of financing and expanding the government relations operation at APA headquarters, including the probable need for a dues increase. That the profession needs more action in the legislative field is manifest, and with it the need for more effective public education programs was recognized.

The editor of *Psychiatric News* was requested to condense the essentials of Dr. Gibson's presentation and to publish it. This has been done.

There was strong reaffirmation of the need for APA to assume more direct and vigorous responsibility for fostering continuing education. Ways must be found to stimulate the individual psychiatrist to accept and pursue his own continuing development.

Topic: New Joint Commission on Mental Illness and Health

The Trustees approved in principle the establishment of a second JCMIH with the intent that it be a joint venture with other organizations and that it focus primarily on the delivery and financing of mental health services and the manpower problem. Deficiencies in the work of the first joint commission were noted, e.g., failure to encompass children, the mentally retarded, and the aging. It was agreed that APA should assume an initiatory and sustained leadership role in delineating the needs of the nation's mentally ill and how these needs can be met.

The Trustees approved appointment of an ad hoc committee to the Council on Mental Health Services. The committee would undertake preliminary planning for a new joint commission with the understanding that the committee would: 1) consider the many points raised by the Trustees in discussing the proposition; 2) assure the Assembly and district branches of input in the planning process; 3) give special attention to the numbers and kinds of organizations, agencies, and consumer representatives that could contribute meaningfully to the planning process; and 4) in general, review the work of the past joint commissions, assess their impact and where we stand now, and project where we want to go and how a new joint commission could help move the profession in that direction. The ad hoc committee was requested to report back in May 1973 with the thought that, at that time, there might have been established a more comprehensive and orderly planning process involving other organizations.

Miscellaneous Actions

Each year the Reference Committee has been requested to study two APA councils and their components in depth and in doing so: 1) to continue to weed out unproductive components; 2) to ensure that priorities on issues be continuously reviewed so that APA's resources may be used most productively and efficiently; and 3) to develop a mechanism by May 1973 to enable each task force and committee to state its objectives, the time needed to complete its task, and the procedures for doing so.

It was agreed that the Executive Committee of the Assembly would designate one member to meet with each of the eight councils to improve effective liaison.

The Trustees accepted the Medical Director's recommendation for procedures to select his successor. The President was requested to appoint a search committee immediately (which has been done), to proceed first with defining the functions of the Medical Director and the qualifications needed to carry them out (to be done by May 1973), and then to recommend candidates who manifest these qualifications (to be done by December 1973).

The Trustees scheduled an additional meeting of their Executive Committee prior to their full meeting at the annual meeting in May. This will free considerable time for the Board to consider policy matters then. The Trustees urged the Executive Committee to meet more often to dispose of routine matters, all to the general end of freeing more time for the Board to consider policy matters.

The Trustees asked the Reference Committee to review the current methods of clearing task force reports for publication. The possibility has been posed of establishing a joint committee with the Assembly for publication review, but the Reference Committee is inclined to believe that the content of task force reports can best be judged by the appropriate council.

The Committee on Constitution and By-Laws was asked to study the relative merits of representing special interest and subspecialty groups on the Board of Trustees (e.g., minorities, women, child psychiatrists, etc.) as opposed to geographic representation. Later, on Feb. 23, 1973, the Executive Committee of the Trustees modified the suggestion by recommending the establishment of an ad hoc committee to study this matter; the committee would be composed of representatives from the Assembly, the Board of Trustees, and the Committee on Constitution and By-Laws.

Position Statement on the Confidentiality of Medical Research Records

This statement was approved by the Board of Trustees of the American Psychiatric Association at its December 8–9, 1972, meeting, upon recommendation of the Council on Research and Development. It was prepared by the Task Force on Confidentiality of Medical Research Records.[1] *The Executive Committee of the Assembly of District Branches endorsed the statement at its meeting on February 17, 1973.*

THE PURPOSE OF THIS STATEMENT is to protect patients and subjects by developing principles that assure the confidentiality of records which might identify the individual patient or subject. Its purpose is also to protect the ethical investigator and those involved with his research against litigious and other punitive actions.

Every investigator and sponsoring agency has an ethical responsibility to preserve the confidentiality of information that might identify the patients or subjects.

A physician, hospital, institution, or agency may release research data only to a professionally qualified and responsible investigator, and only if such data are essential. Identifying data should never be released without the knowing consent of the patient, his guardian, or his survivor.

The investigator should explain to the patient or subject the extent of the confidentiality of the information furnished. If identifying data may be of potential interest to civil, criminal, or administrative authorities, the investigator should, wherever possible, obtain a written waiver in advance from the officials concerned. If there is a court order to divulge such information, it should be released only after a thorough and proper judicial review of the facts.

Before authorizing transfer of *any* data to other research personnel the investigator must *receive assurance in writing* that the aforementioned principles will be followed.

Modern data processing systems create problems in the application of these principles. The primary responsibility for ensuring the confidentiality of records rests with the investigator regardless of the method by which such records are stored.

Federal and state legislation should be enacted that implements these stated principles. The task force felt that the statutes enacted by various states offered many good suggestions, particularly the Maryland Annotated Code, Article 43 Section 149-C (1957-Repl. Vol. 1969); Article 35 Section 102, and Article 75-C Section 11; and the Connecticut Public Acts (1969), Public Act Number 819 Sections 5 and 6. These represent good examples of sound, useful, and workable legislation that may serve as general models. The task force suggests, however, stronger sanctions for instances when these laws are abused.

[1]The task force included: Jonas R. Rappeport, M.D., chairman; Sidney Merlis, M.D.; Henry A. Davidson, M.D.; Gerald D. Klee, M.D.; A. Louis McGarry, M.D.; and William Curran, LL.D., and Everett Goldberg, LL.B., consultants.

Position Statement on College Mental Health

This statement was approved by the Board of Trustees of the American Psychiatric Association at its December 8–9, 1972, meeting, upon recommendation of the Council on Medical Education and Career Development. It was prepared by the Task Force on College Mental Health.[1] *The Executive Committee of the Assembly of District Branches endorsed the statement at its meeting on February 17, 1973.*

THE TASK FORCE RECOGNIZES that, for many years, psychiatrists have played a significant role in institutions of higher learning in this country. Higher education is facing major challenges and changes. It is crucial that institutions and psychiatrists who work in them be aware of the impact these changes have on the growth and development of the individual.

In the clinical situation the psychiatrist typically focuses on the individual's response to both internal and environmental factors and attempts to help the individual deal with these factors. The psychiatrist working in the college setting has a particular obligation to recognize those institutional conditions which affect individual functioning, both adversely and positively. With this understanding he has the opportunity to contribute significantly to the process of constructive change. Both of these opportunities—to assist the individual and the institution—are essential components of the psychiatrist's role on campus.

There are conditions essential to the effective implementation of each of these tasks or opportunities. Psychotherapy on campus has obvious similarities to other psychiatric clinical situations, but there are also some important differences. These include: accessibility without the necessary definition of "patient role"; rapidity and appropriateness of the professional response to the felt need of the individual who is requesting help; particular attention to policies of confidentiality; recognition that problems of the student age group may be more responsive to minimal intervention; and the special importance of understanding the social context in which the patient moves.

In assisting the institution toward constructive change the psychiatrist must be aware of the sensitivity of his position. It is essential that his activities be conducted in such a way that individual confidences are absolutely protected. Other factors relevant to this second task of consultation include: a high degree of personal visibility on campus; accepting the limits of one's competency, especially in unfamiliar, nonpsychiatric areas; defining and clarifying problems on campus; and facilitating communication on campus. The psychiatrist can influence matters of policy in the college community. However, he is not the only professional involved in these matters, and mental health factors are not the only ones contributing to policy decisions.

The task force recognizes that only a few psychiatrists will work full-time in college health settings. Others may work part-time on campus or see individual patients in their offices off campus. It is important that all such groups of psychiatrists become aware of the stated issues.

[1]The task force included: James R. Raybin, M.D., chairman; Robert L. Arnstein, M.D.; Seymour L. Halleck, M.D.; Clifford B. Reifler, M.D.; Bensor R. Snyder, M.D.; and James Banning, M.D., consultant.

Joint Statement on Antisubstitution Laws and Regulations

The American Medical Association asked APA to join other organizations in approving this joint statement. The statement was approved by the Board of Trustees of the American Psychiatric Association at its meeting on February 23, 1973. As of the end of March 1973, 11 organizations,[1] including APA and AMA, had approved this statement.

THE PURPOSE OF THIS STATEMENT is to affirm the support of the participating organizations for the laws, regulations, and professional traditions that prohibit the unauthorized substitution of drug products.

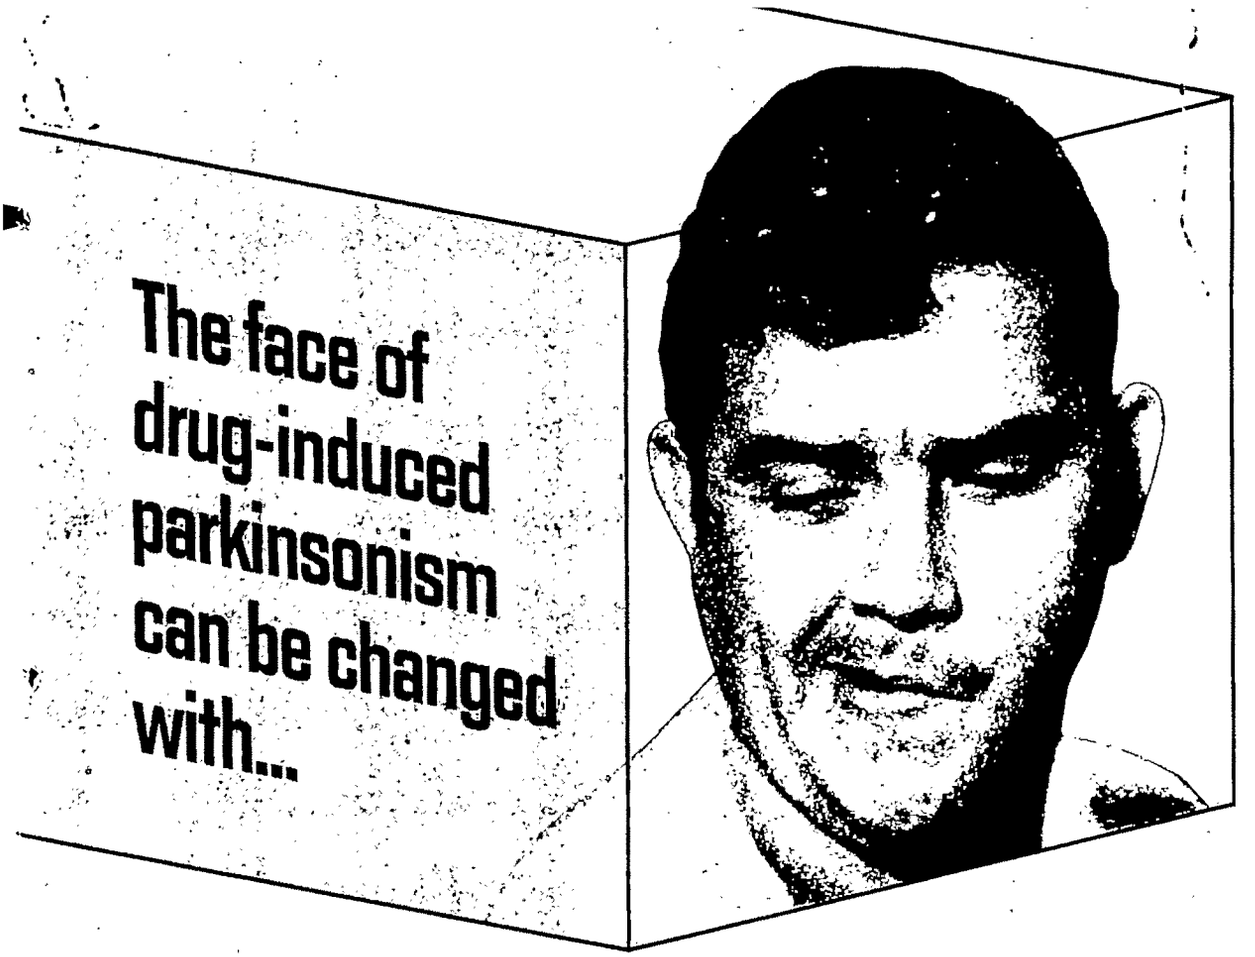
Traditionally, physicians, dentists, and pharmacists have worked cooperatively to serve the best interests of patients. Productive cooperation has been achieved through mutual respect, as well as through a common concern for the ideals of public service. This mutual respect has been reflected, in part, by joint support over the years for the adoption and enforcement of laws and regulations specifically prohibiting unauthorized substitution and encouraging joint discussion and selection of the supply source of drug products. The basic principles of medical, dental, and pharmaceutical practice are thus utilized and preserved in the interests of patient welfare.

The antisubstitution laws have not obstructed enhancement of the professional status of pharmacy any more than they have, in and of themselves, guaranteed absolute protection from unsafe drugs or have freed physicians, dentists, and pharmacists from their responsibilities to patients. As a practical matter, however, such laws and regulations encourage interprofessional communications regarding drug product selection and assure each profession of the opportunity to exercise fully its expertise in drug usage to the patients' advantage.

Physicians and dentists should be urged to increase the frequency and regularity of their contacts with pharmacists in selecting quality drug products, recognizing that economies to patients can be improved through such communication and taking into account the patients' needs. The pharmacists' knowledge of the chemical characteristics of drugs, their mode of action, toxic properties, and other characteristics that assist in making drug selection decisions should be utilized to the fullest extent practicable by physicians and dentists in serving their patients.

Since drug product selection entails knowledge derived from clinical experience, the physician's role in product selection remains primary and does not permit delegation of decisions requiring medical judgment. A broader role in therapy will evolve for pharmacists as improved understanding and cooperation between the two professions continue to grow.

There has been no evidence that convincing reasons exist to modify or to repeal existing laws and regulations prohibiting the unauthorized substitution of one drug product for the drug product specified by a prescriber. It is our belief that such laws and regulations merit the joint support of the medical, dental, and pharmaceutical professions and of the pharmaceutical industry.



[1] The organizations are: the American College of Obstetricians and Gynecologists, the American College of Physicians, the American Academy of Neurology, the American College of Allergists, the American Dental Association, the American College of Cardiology, the American Academy of Dermatology, the American Academy of Family Physicians, the American Academy of Pediatrics, the American Medical Association, and the American Psychiatric Association.

Prompt Publication Policy

The *Journal* would like to remind those authors who are particularly interested in early publication (whether to establish priority of an idea, reveal innovative results of new research, or for other pressing reasons) of its prompt publication policy, first announced in the April 1971 issue (p. 1399) as follows:

"The *Journal* would consider publishing very short (two-to-four-page) manuscripts in the first available issue. Of course, these manuscripts will still have to undergo expert scrutiny before being accepted, and two months must be allowed for the printing process, but we think we can considerably shorten the time required for the publication of these very short articles, which will be included in the Brief Communications section."

Authors who would like to have their manuscripts considered under this policy should indicate this desire, as well as the reasons for it, when they submit their manuscripts.

AKINETON®
(biperiden)

- relieves extrapyramidal reactions
- reduces akinesia and rigidity
- combines well with other anti-parkinson agents
- more than ten years of clinical experience

WARNINGS, PRECAUTIONS, ADVERSE REACTIONS: Isolated instances of mental confusion, euphoria, agitation and disturbed behavior have been reported in susceptible patients. Use with caution in manifest glaucoma, prostatism and cardiac arrhythmia. Dry mouth, blurred vision and drowsiness appear infrequently. Some decrease in urinary flow has been noted in a few patients. If gastric irritation occurs, it may be avoided by administering during or after meals. With parenteral administration, mild transient postural hypotension may be evidenced. The only known contraindication is sensitivity to Akineton (biperiden.) DOSAGE: Orally: **Parkinsonism:** 1 tablet, 2 mg., 3 or 4 times daily. **Drug-induced extrapyramidal disorders:** 1 tablet, 2 mg., 1 to 3 times daily. Parenterally: the average adult dose is 2 mg. intramuscularly or intravenously. May be repeated every half-hour until resolution of symptoms is effected, but not more than 4 consecutive doses should be administered in a 24-hour period. SUPPLIED: Tablets—2 mg. (bisected) Akineton HCl. Ampules—1 ml. containing 5 mg. Akineton lactate in an aqueous 1.4% sodium lactate solution.

KNOLL PHARMACEUTICAL COMPANY · WHIPPANY, NEW JERSEY 07981 · TORONTO, CANADA

Help release her from severe anxiety. Then she can open up to you.

Only with relief of the severe anxiety that often blocks verbalization can many patients expect to progress in therapy. To this end, Serax may prove beneficial, for it is now well established as an effective antianxiety adjunct. Serax offers flexibility as well. Dosage can be readily adjusted to individual needs. To the point where the patient may frequently resume normal work activities.

As with other CNS-acting drugs, patients should be cautioned against driving automobiles or operating dangerous machinery until it is known that they do not become drowsy or dizzy on oxazepam therapy. When prescribing, carefully observe dosage recommendations and appropriate precautions, especially as pertaining to the elderly or where a drop in blood pressure might lead to cardiac complications.

In severe anxiety

Serax®

(oxazepam)

Wyeth Laboratories
Philadelphia, Pa. 19101

Please see important information on page after next.

Help release her from severe anxiety.

Indications: Oxazepam is indicated for the management and control of anxiety, tension, agitation, irritability and related symptoms. Such symptoms are commonly seen in patients with a diagnosis of psychoneurotic reaction, psychophysiological reaction, personality disorder, or in patients with underlying organic disease.

Anxiety associated with depression is also responsive to oxazepam therapy.

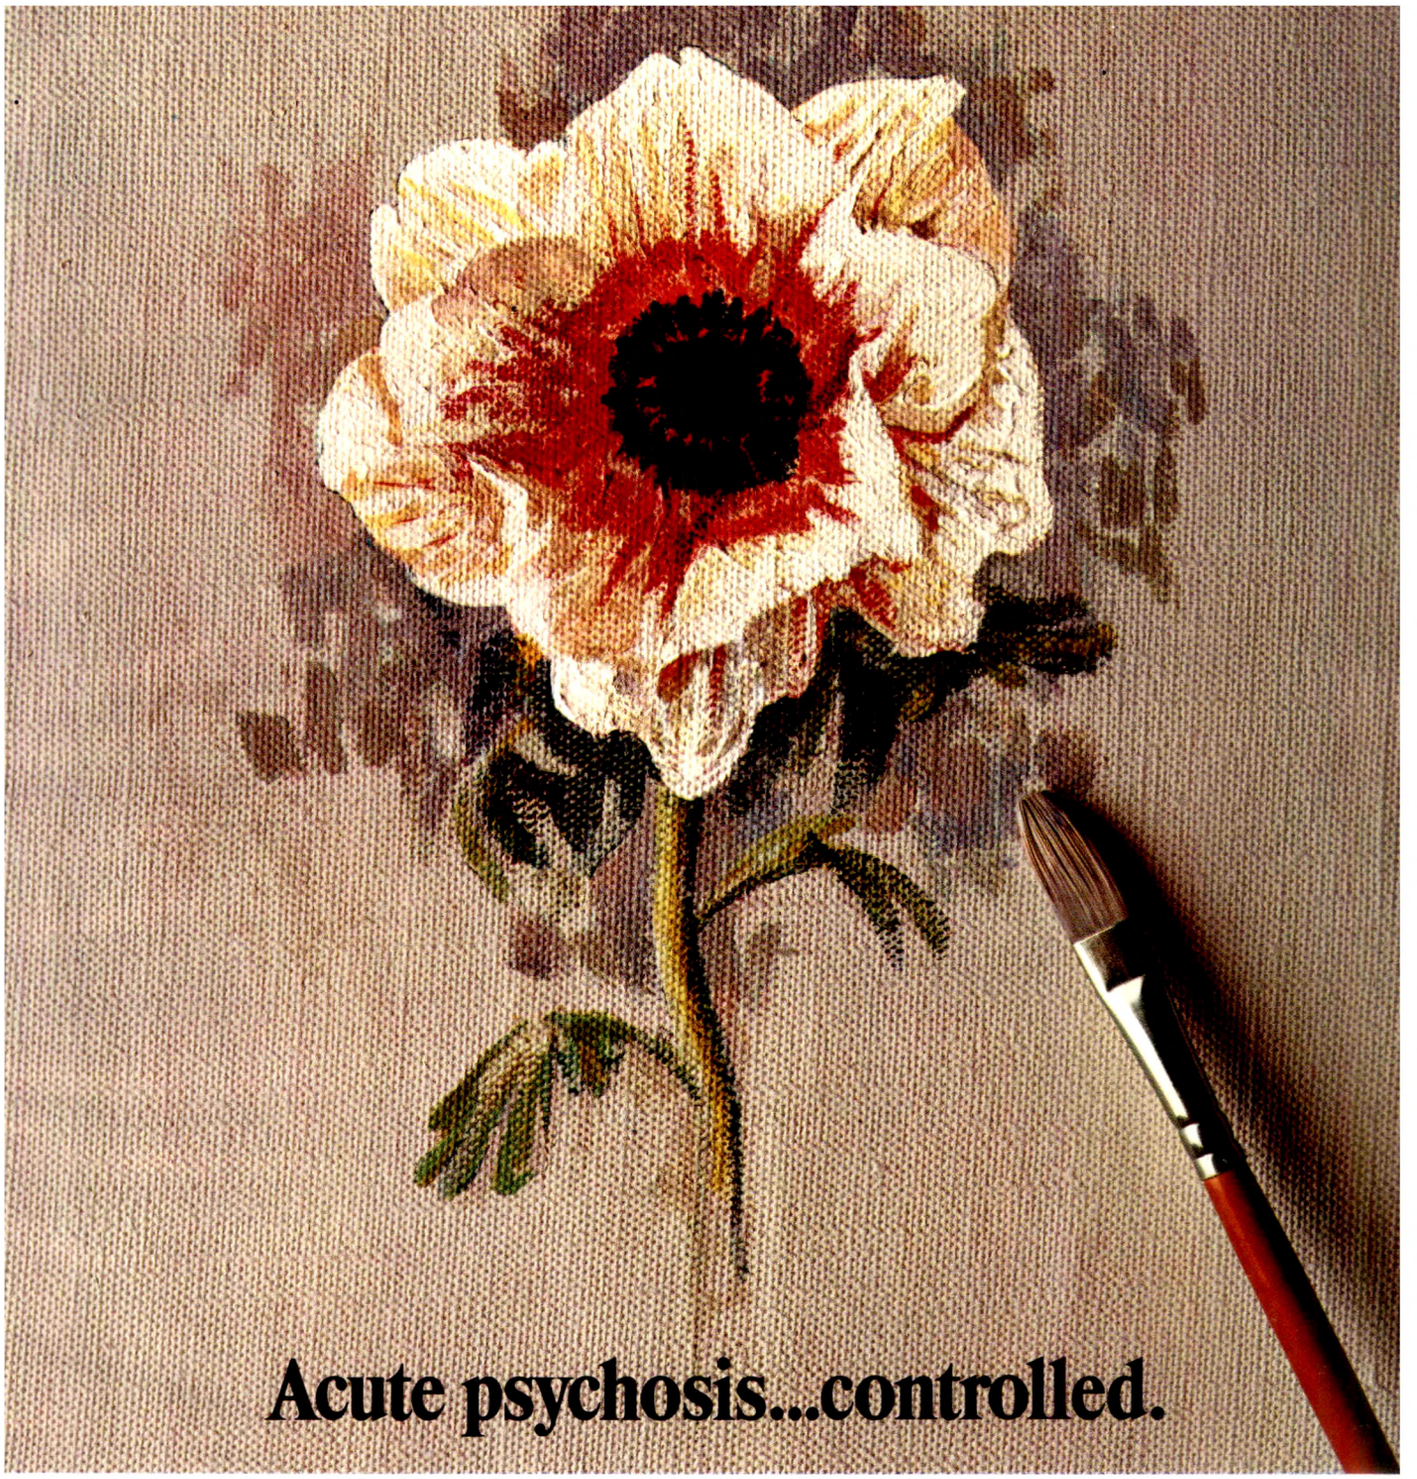
This product has been found particularly useful in the management of anxiety, tension, agitation and irritability in older patients.

Alcoholics with acute tremulousness, inebriation or with anxiety associated with alcohol withdrawal are responsive to therapy.

Contraindications: History of previous hypersensitivity to oxazepam. Oxazepam is not indicated in psychoses.

Warning: *Use in Pregnancy:* Safety for use in pregnancy not established.

Precautions: Hypotensive reactions are rare, but use with caution where complications could ensue from a fall in blood pressure, especially in the elderly. Withdrawal symptoms upon discontinuation have been noted in some patients exhibiting drug dependence through chronic overdose. Carefully supervise dose and amounts prescribed, especially for patients prone to self-overdose; excessive, prolonged use in susceptible patients (alcoholics, ex-addicts, etc.) may result in dependence or habituation. Reduce dosage gradually after prolonged excessive dosage to avoid possible epileptiform seizures. Withdrawal symptoms following abrupt discontinuance are similar to those seen with barbiturates. Caution patients against driving or operating machinery until absence of drowsiness or dizziness is ascertained. Warn patients of possible reduction in alcohol tolerance.



Not indicated in children under 6 years; absolute dosage for 6- to 12-year-olds not established.

Adverse Reactions: Therapy-interrupting side effects are rare. Transient mild drowsiness is common initially; if persistent, reduce dosage. Dizziness, vertigo and headache have also occurred infrequently; syncope, rarely. Mild paradoxical reactions (excitement, stimulation of affect) are reported in psychiatric patients. Minor diffuse rashes (morbilliform, urticarial and maculopapular) are rare. Nausea, lethargy, edema, slurred speech, tremor and altered libido are rare and generally controllable by dosage reduction. Although rare, leukopenia and hepatic dysfunction including jaundice have been reported during therapy. Periodic blood counts and liver function tests are advised. Ataxia, reported rarely, does not appear related to dose or age. These side reactions, noted with related compounds, are not yet reported: paradoxical excitation with severe rage reactions, hallucinations, menstrual irregularities, change in EEG pattern, blood dyscrasias (including agranulocytosis), blurred vision, diplopia, incontinence, stupor, disorientation, fever and euphoria.

Availability: Capsules of 10, 15 and 30 mg. oxazepam; tablets of 15 mg. oxazepam.

Serax®
(oxazepam)

Wyeth Laboratories
Philadelphia, Pa. 19101

Navane (thiothixene) helps reduce the intensity and frequency of acute psychotic symptoms. With Navane, confusion, disorientation and other manifestations of acute psychosis may be controlled. And, as acute symptomatology decreases, the patient may be better able to readjust to therapeutic, family and community relationships and responsibilities. Navane...an effective anti-psychotic for acute psychosis.

ROERIG Pfizer
A division of Pfizer Pharmaceuticals
New York, New York 10017

Navane®

(thiothixene) (thiothixene hydrochloride)

Capsules 1 mg., 2 mg., 5 mg., 10 mg. Concentrate 5 mg./cc., Intramuscular 2 mg./cc.

to help control psychotic behavior

For prescribing information, including adverse reactions and contraindications, please see following page of this advertisement.

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg., 2 mg., 5 mg., 10 mg.
Concentrate: 5 mg./cc.
Intramuscular: 2 mg./cc.

PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules 1 mg., 2 mg., 5 mg., 10 mg.
(thiothixene hydrochloride)
Concentrate 5 mg./cc., Intramuscular 2 mg./cc.

Actions. Navane is a psychotropic agent of the thioxanthene series. Navane possesses certain chemical and pharmacological similarities to the piperazine phenothiazines and differences from the aliphatic group of phenothiazines. Navane's mode of action has not been clearly established.

Indications. Navane is effective in the management of manifestations of psychotic disorders.

Contraindications. Navane is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy* – Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane (thiothixene), there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration to rats (5 to 15 mg./kg./day), rabbits (3 to 50 mg./kg./day), and monkeys (1 to 3 mg./kg./day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in children—The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane (thiothixene) may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane [thiothixene] for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis), have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration – As with all intramuscular preparations, Navane (thiothixene hydrochloride) Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the midlateral thigh.

The deltoid area should be used only if well developed such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower- and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following reactions have been reported with Navane. However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane (thiothixene) is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur, although it usually subsides with continuation of Navane therapy. The incidence of sedation appears to be similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane. Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudoparkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: Although not reported with Navane, certain antipsychotic agents have been associated with persistent dyskinesias. Tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane (thiothixene) have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leucocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration because safe conditions for its use have not been established.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Usage in children under 12 years of age is not recommended.

Navane Intramuscular Solution—For Intramuscular Use Only. Where more rapid control and treatment of behavior is desirable, the intramuscular form of Navane (thiothixene hydrochloride) may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg. of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg./day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane Capsules and Concentrate appear in the following paragraphs.

Navane Capsules: Navane Concentrate—In milder conditions, an initial dose of 2 mg. three times daily. If indicated, a subsequent increase to 15 mg./day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg. twice daily.

The usual optimal dose is 20 to 30 mg. daily. If indicated, an increase to 60 mg./day total daily dose is often effective. Exceeding a total daily dose of 60 mg. rarely increases the beneficial response.

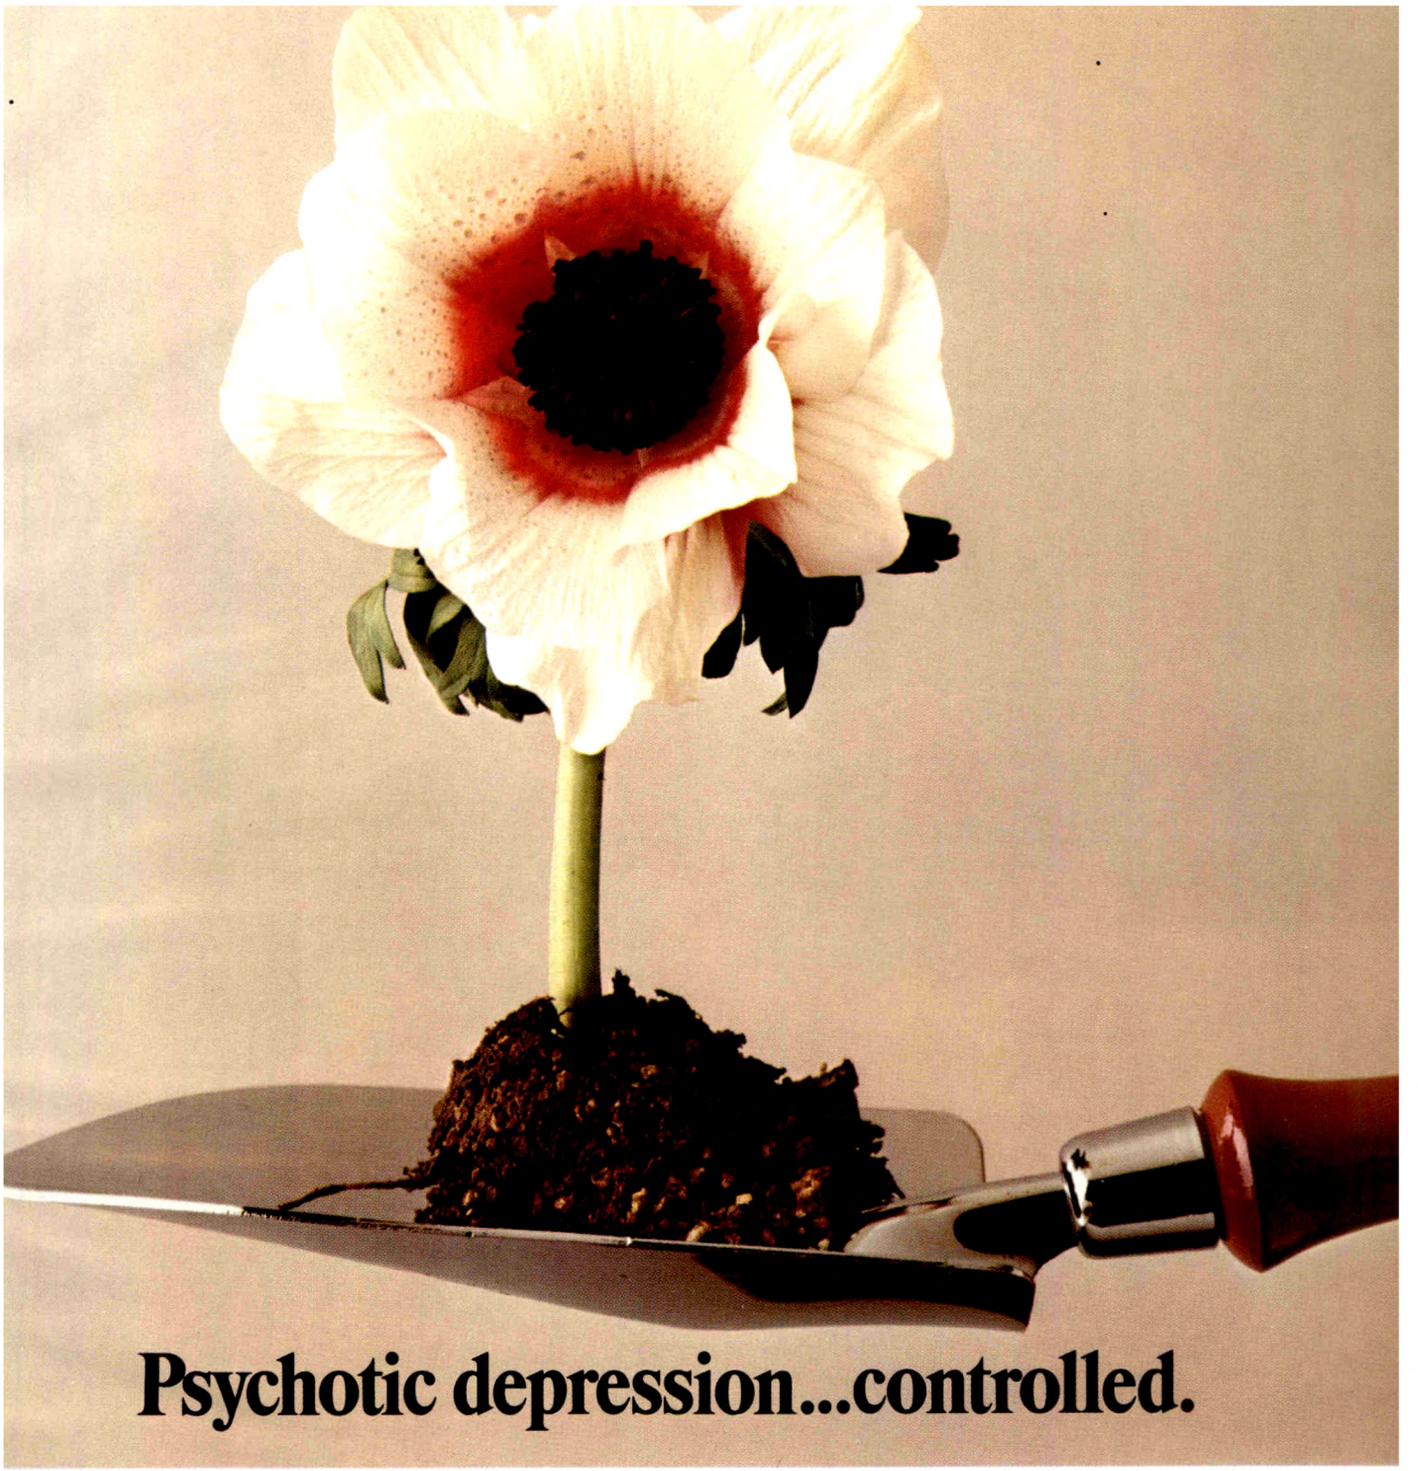
Some patients have been successfully maintained on once-a-day Navane (thiothixene) therapy.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Picrotoxin or pentylenetetrazol should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.



There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg., 2 mg., 5 mg., and 10 mg. in bottles of 100 and 1,000.

Navane (thiothixene hydrochloride) Concentrate is available in 120 cc. (4 oz.) bottles with an accompanying dropper calibrated at 2 mg., 4 mg., 5 mg., 6 mg., 8 mg. and 10 mg. Each cc. contains thiothixene hydrochloride equivalent to 5 mg. of thiothixene. Contains alcohol, U.S.P. 7.0% v/v. (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular Solution is available in a 2 cc. amber glass vial in packages of 10. Each cc. contains thiothixene hydrochloride equivalent to 2 mg. of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v.

Navane®

(thiothixene) (thiothixene hydrochloride)

Capsules 1 mg., 2 mg., 5 mg., 10 mg. Concentrate 5 mg./cc., Intramuscular 2 mg./cc.

to help control psychotic depression

For prescribing information, including adverse reactions and contraindications, please see facing page of this advertisement.

HELPS KEEP THE REAL IN REALITY

Effective Management of Psychotic Symptoms

- Calms hyperactive behavior
- Controls hostility
- Decreases delusions, auditory and visual hallucinations
- Allays underlying fear, anxiety and tension
- Lessens unusual thought content, paranoid ideation
- Reduces emotional withdrawal

Before prescribing, see complete prescribing information including dosage and symptoms and treatment of overdosage, in SK&F literature or *PDR*.

Indications
Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of manifestations of psychotic disorders.

Probably effective: For control of the manifestations of manic-depressive illness (manic phase). For the control of moderate to severe agitation, hyperactivity or aggressiveness in disturbed children.

Possibly effective: For control of excessive anxiety, tension and agitation as seen in neuroses.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose states, presence of large amounts of C.N.S. depressants, or bone marrow depression.

Warnings: Avoid using in patients hypersensitive (e.g., blood dyscrasia, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy. Avoid concomitant use with alcohol. May counteract antihypertensive effect of guanethidine and related compounds.

Use in pregnancy only when essential. There are reported instances of jaundice or prolonged extrapyramidal signs in newborn whose mothers had received chlorpromazine.

Precautions: Use cautiously in persons with cardiovascular, liver or chronic respiratory disease, or with acute respiratory infections. Due to cough reflex suppression, aspiration of vomitus is possible. May prolong or intensify the action of C.N.S. depressants, organophosphorus insecticides, heat, atropine and related drugs. (Reduce dosage of concomitant C.N.S. depressants.) Anticonvulsant action of barbiturates is not intensified. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Discontinue high-dose, long-term therapy gradually.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, cholestatic jaundice, agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura and pancytopenia; postural hypotension, tachycardia, fainting, dizziness and, occasionally, a shock-like condition; reversal of epinephrine effects; EKG changes have been reported, but relationship to myocardial damage is not confirmed; neuromuscular (extrapyramidal) reactions; pseudoparkinsonism, motor restlessness, dystonias, persistent tardive dyskinesia, hyperreflexia in the newborn; psychotic symptoms, catatonic-like states, cerebral edema; convulsive seizures; abnormality of the cerebrospinal fluid proteins; urticarial reactions and photosensitivity, exfoliative dermatitis, contact dermatitis; lactation and breast engorgement (in females on large doses), false positive pregnancy tests, amenorrhea, gynecomastia; hyperglycemia, hypoglycemia, glycosuria; dry mouth, nasal congestion, constipation, adynamic ileus, urinary retention, miosis, mydriasis; after prolonged substantial doses, skin pigmentation, epithelial keratopathy, lenticular and corneal deposits and pigmentary retinopathy, visual impairment; mild fever (after large I.M. dosage); hyperpyrexia; increased appetite and weight; a systemic lupus erythematosus-like syndrome; peripheral edema. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 10 mg., 25 mg., 50 mg., 100 mg. and 200 mg., in bottles of 100; Spansule® capsules, 30 mg., 75 mg., 150 mg., 200 mg. and 300 mg., in bottles of 50; Injection, 25 mg./ml.; Syrup, 10 mg./5 ml.; Suppositories, 25 mg. and 100 mg.; Concentrate, 30 mg./ml. and 100 mg./ml.

THORAZINE®

brand of

C LOR ROMAZI E Tablets: 50 mg. of the HCl

Th TRIAVIL® Pot ntial in the management of moderate to severe anxiety with depression

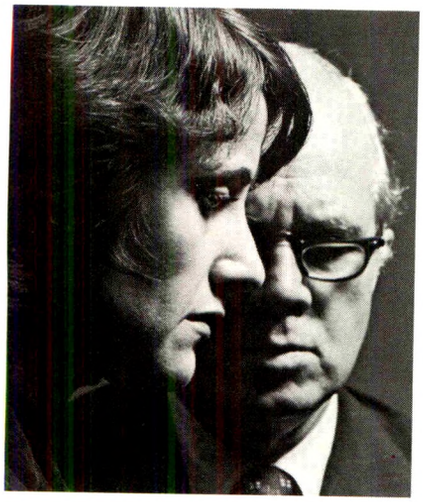
When time and talk are not enough...
The therapist is the primary catalyst for change in the psychotherapeutic relationship. However, when patients suffer from moderate to severe anxiety with depression, there are situations when TRIAVIL can often be a useful adjunct.

...TRIAVIL may help
There are three important benefits you may expect when TRIAVIL is part of the treatment program: (1) When symptoms of moderate to severe anxiety or agitation with depression are relieved, the patient may become more accessible and cooperative. (2) As somatic manifestations are controlled, attention may be focused on underlying causative factors. (3) Symptomatic relief may enable the patient to function more effectively in his daily life while your work with the patient progresses.

Since it is simpler to remember to take one tablet rather than several (particularly in multiple daily doses), your patients on TRIAVIL will be more likely to take proper doses of the medication. And, of course, economy is an added factor in therapy with TRIAVIL.

Tablets TRIAVIL are available in four different combinations affording flexibility and individualized dosage adjustment. Close supervision of patients is essential until satisfactory remission has taken place. Suicide is inherent in any depressive illness so patients should not have easy access to large quantities of the drug. The drug may impair alertness and potentiate the response to alcohol. It should not be used during the acute recovery phase following myocardial infarction or given to patients who have received an MAOI within two weeks. TRIAVIL should be used with caution in glaucoma and in patients prone to urinary retention. It is contraindicated in CNS depression and in the presence of evidence of bone marrow depression.

MSD
MERCK SHARP & DOHME



For a brief summary of prescribing information, please turn to the following page.

when patients exhibit moderate to marked anxiety or agitation with symptoms of depression

TRIAVIL® (containing perphenazine and amitriptyline HCl)

an antidepressant tranquilizer

when patients exhibit moderate to marked anxiety
or agitation with symptoms of depression

TRIAVIL® 4-25

Each tablet contains
4 mg. perphenazine and
25 mg. amitriptyline HCl

a formulation particularly suited to psychiatric practice when higher doses are required.

Also Available:
TRIAVIL® 2-25: Each tablet contains
2 mg. perphenazine and 25 mg. amitriptyline HCl.

TRIAVIL® 2-10: Each tablet contains
2 mg. perphenazine and 10 mg. amitriptyline HCl.

TRIAVIL® 4-10: Each tablet contains
4 mg. perphenazine and 10 mg. amitriptyline HCl.

INITIAL THERAPY FOR MANY PATIENTS
TRIAVIL® 2-25 (or TRIAVIL® 4-25) t.i.d. or q.i.d.

FOR FLEXIBILITY IN ADJUSTING MAINTENANCE THERAPY
TRIAVIL® 2-10 (or TRIAVIL® 4-10)

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, narcotics, analgesics, antihistamines) and alcohol; bone marrow depression; pregnancy; known hypersensitivity to phenothiazines or amitriptyline. Do not give concomitantly with MAOI drugs because hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. Allow minimum of 14 days between therapies, then initiate therapy with TRIAVIL cautiously, with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction. Not recommended in children.

WARNINGS: TRIAVIL should not be given with guanethidine or similarly acting compounds. Use cautiously in patients with history of urinary retention, narrow-angle glaucoma, increased ocular pressure, or convulsive disorders. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, particularly in high doses, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. Caution patients performing hazardous tasks, such as operating machinery or driving motor vehicles, that drug may impair mental and/or physical abilities.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.
Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of untoward actions is greater with high doses. Closely supervise with any dosage.
The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction.
A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.
If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine.
Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides.
Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant drug. Patients with paranoid symptomatology may have an exaggeration of such symptoms.
The tranquilizing effect of TRIAVIL has seemed to reduce the likelihood of this effect.
Supervise closely and carefully adjust dosage when given with anticholinergic agents and sympathomimetic drugs.
The drug may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.
Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards of therapy. Such treatment should be limited to patients for whom it is essential.
Discontinue several days before elective surgery if possible.
Elevation and lowering of blood sugar levels have both been reported.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.
Perphenazine: Side effects may be any of those reported with phenothiazine drugs: extrapyramidal symptoms (opisthotonos, oculogyric crises, hyperreflexia, dystonia, akathisia, dyskinesia, parkinsonism) usually controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine; skin disorders (photosensitivity, itching, erythema, urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reaction); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galac-

torrhea, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dryness of the mouth, headache, nausea, vomiting, constipation, obstipation, urinary frequency, blurred vision, nasal congestion, and a change in pulse rate; hypnotic effects; pigmentary retinopathy; corneal and lenticular pigmentation; occasional lassitude; muscle weakness; mild insomnia. Other adverse reactions reported with various phenothiazine compounds include blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia); liver damage (jaundice, biliary stasis); grand mal convulsions; cerebral edema; polyphagia; photophobia; skin pigmentation; and failure of ejaculation.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitivity; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness; weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; jaundice; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

For more detailed information, consult your MSD Representative or see full Prescribing Information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486.

MSD
MERCK SHARP & DOHME

Addendum

A suggested four-point rating scale to help evaluate patient progress week-to-week or month-to-month when presenting symptoms include anxiety or agitation with depression.

Mood—degree of depression (facial expression, voice quality, conversation content).

1. Continued profound depression, feelings of hopelessness.
2. Feeling "blue," chronic pessimism, rare cheerfulness.
3. Appropriate cheerfulness, slight depression, diluted pleasure capacity.
4. Appropriate cheerfulness and optimism.

Psychomotor Activity—reflective of emotional pressure (hypoactive patient).

1. Immobile, not fulfilling daily responsibilities.
2. Generalized slowness, constant fatigue.
3. Appropriate motor activity in most instances.
4. Activity appropriate in degree and duration to environmental stimuli.

Performance — vocational.

1. Unable to perform at all.
2. Works intermittently with difficulty.
3. Full-time employment, moderate pride in achievements.
4. Full-time employment, functioning efficiently, deriving pleasure from achievements.

Anxiety Amelioration — in terms of motor, affective, autonomic and verbal phenomenon.

1. Panic, incessant movement, state of terror.
2. Moderate restlessness, pacing, moderate expression of fear.
3. Slight restlessness, slight affective expression of fear.
4. Calm, no restlessness, expression of fear (when it occurs) appropriate to severity of stress.

Amelioration of Symptoms

1. Symptoms unchanged or worse.
2. Fair, slight improvement, patient still plagued with symptoms.
3. Symptoms markedly reduced in intensity and frequency, able to cope.
4. All presenting symptoms gone.

Adapted from Lesse, S.: Anxiety, Its Components, Development and Treatment, Grune & Stratton, New York, 1970.

R.S.V.P.

She just doesn't respond to things. No interest. No energy. Discouraged.

It may be mild depression. She needs help...and she needs it now.

Counsel and reassurance may suffice. But if you decide supportive medication is indicated, Ritalin can offer prompt benefit.

Ritalin usually begins to act with the very first dose...boosts spirits and brightens mood...helps the patient get moving again. And Ritalin is generally well tolerated, even by older and convalescent patients. However, Ritalin should not be used for severe depression.

When Ritalin works, one prescription may be enough... to help provide an answer to mild depression.

Ritalin®
(methylphenidate) helps the patient respond in mild depression*

Ritalin® hydrochloride ℂ
(methylphenidate hydrochloride)

TABLETS

INDICATION
Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indication as follows:
"Possibly" effective: Mild depression
Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS
Marked anxiety, tension, and agitation, since Ritalin may aggravate these symptoms. Also contraindicated in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS
Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.
Sufficient data on safety and efficacy of long-term use of Ritalin in children with minimal brain dysfunction are not yet available.
Although a causal relationship has not been established, suppression of growth (*ie*, weight gain and/or height) has been reported with long-term use of stimulants in children. Therefore, children requiring long-term therapy should be carefully monitored.
Ritalin should not be used for severe depression of either exogenous or endogenous origin or for the prevention of normal fatigue states.
Ritalin may lower the convulsive threshold in patients with or without prior seizures; with or without prior EEG abnormalities, even in absence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. If seizures occur, Ritalin should be discontinued.
Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.
Drug Interactions
Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors. Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.
Usage in Pregnancy
Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence
Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.

Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS
Patients with an element of agitation may react adversely; discontinue therapy if necessary.
Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

ADVERSE REACTIONS
Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include: hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported.
Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; a few instances of scalp hair loss.
In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION
Adults
Administer orally in divided doses 2 or 3 times daily, preferably 30 to 45 minutes before meals. Dosage will depend upon indication and individual response.
Average dosage is 20 to 30 mg daily. Some patients may require 40 to 60 mg daily. In others, 10 to 15 mg daily will be adequate. The few patients who are unable to sleep if medication is taken late in the day should take the last dose before 6 p.m.

HOW SUPPLIED
Tablets, 20 mg (peach, scored); bottles of 100 and 1000.
Tablets, 10 mg (pale green, scored); bottles of 100, 500, 1000 and Accu-pak blister units of 100.
Tablets, 5 mg (pale yellow); bottles of 100, 500 and 1000.
Consult complete product literature before prescribing.

*This drug has been evaluated as possibly effective for this indication. See brief prescribing information.

CIBA

The balanced approach in adjunctive drug therapy

Especially relevant in psychiatric practice

The role of anxiety as a psychodynamic force is generally acknowledged, although psychiatrists may differ as to its definition, origin and management. The intensity of anxiety may at times require adjunctive drug therapy for prompt relief of intolerable suffering; abatement of emotional tension, so that rapport and verbal communication may be expedited; and breaking down of stubborn resistances so that maladaptive behavior may

be examined.

But anxiety—in moderation an appropriate accompaniment of growth—need not and should not be diminished to the point of extinguishing its *signal* function.

Drug and dosage should be selected so as to allow the maintenance and continuation of a reasonable amount of anxiety as an incentive to motivate participation in psychotherapy and to encourage problem-solving on the patient's own initiative. In this context, the so-called minor tranquilizers, in contrast to major tranquilizers, exhibit a well-tolerated, predominantly anti-anxiety action. Thus, when drug therapy of obstructive anxiety is required, a suitable minor tranquilizer is often recommended.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported. Use of any drug in pregnancy, lactation, or in women of childbearing age requires that its potential benefits be weighed against its possible hazards.

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of

Antianxiety action without exaggerated effect

Librium (chlordiazepoxide HCl) dosage meets patient needs

The benzodiazepines are regarded as among the safer and more effective of the antianxiety drugs available. Adjunctive Librium enjoys extensive use in the treatment of clinically significant anxiety. It should be employed flexibly, titrated to the degree of anxiety being experienced by the individual patient. The dosage schedule should have as its goal the maximum relief of disruptive anxiety; when that

has been accomplished, Librium (chlordiazepoxide HCl) therapy should be discontinued. Experience has shown that Librium, in proper dosage, seldom impairs mental acuity or performance. (See Warnings section below.)

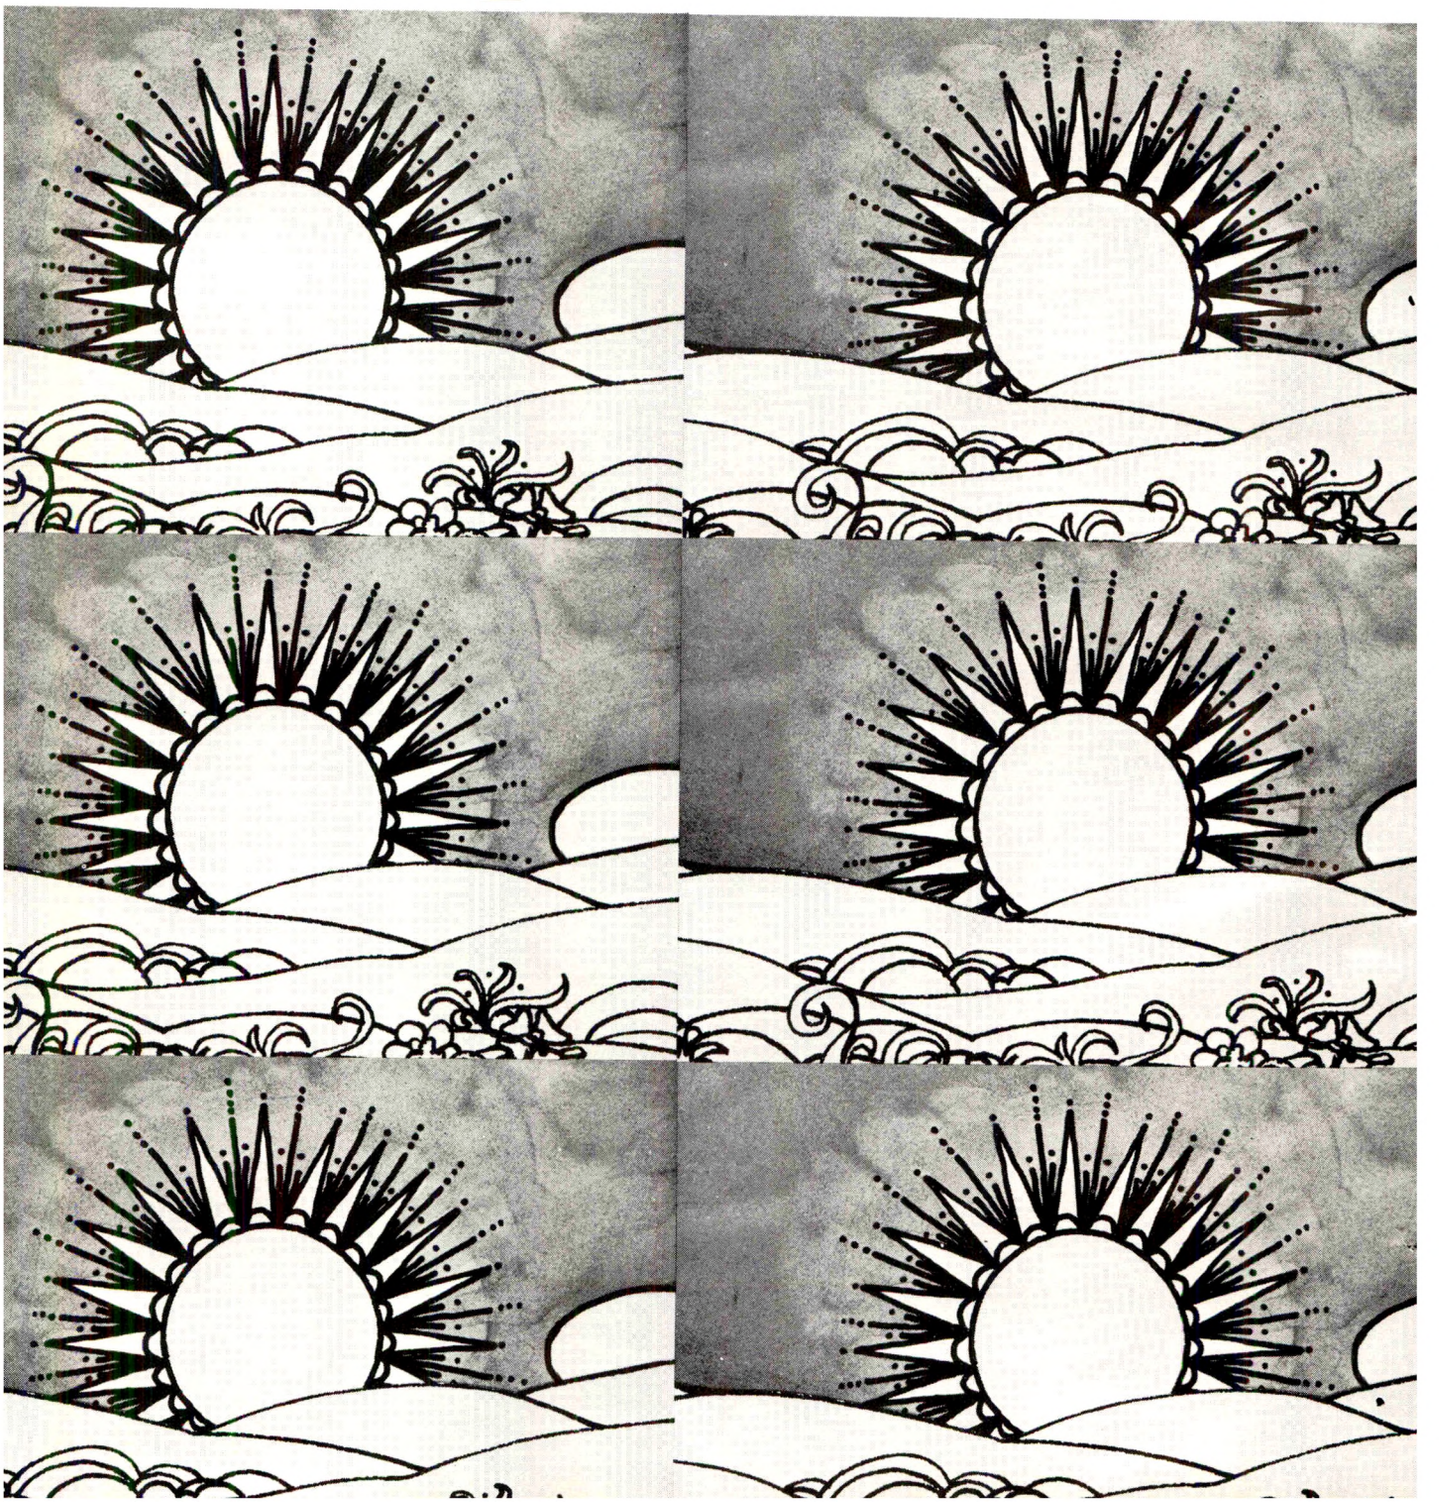
Drowsiness, ataxia and confusion are the most common side effects reported, most notably in the elderly or debilitated. Thus, Librium is especially valuable in treating anxiety in the neurotic ambulatory patient with daily responsibilities to fulfill. In most cases, Librium can promptly reduce excessive anxiety to less disruptive levels, making a rational approach to discussion of disturbing psychic material more possible, and encouraging a more positive resolution of the patient's emotional problems.

for control of inappropriate anxiety

Librium®
(chlordiazepoxide HCl)

10-mg, 25-mg capsules t.i.d./q.i.d.

ROCHE



Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, N.J. 07110

impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido —all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.

The new-day constant for drug-induced parkinsonism:

ARTANE®
TRIHEXYPHENIDYL HCl

Non-cumulative action makes each day of therapy a new day

That's why ARTANE is ideally suited for the patient on long-term phenothiazine therapy. In economical tablets or SEQUELS Sustained Release Capsules*, it offers you *more* than the rapid reversal of extrapyramidal symptoms.

Usually there is no drug buildup to cause undue toxicity in prolonged therapy. Minimal atropine-like side effects. Accurate dosage titration in adjunctive use. And, to minimize missed doses and anxiety in outpatient therapy— one-dose *all-day* control or prevention with SEQUELS.*

For hospitalized or ambulatory patients, ARTANE has the "constant" they need. Effective *non-cumulative* action.

Tablets—2 mg, 5 mg; Elixir†—2 mg/5 cc or SEQUELS® Sustained Release Capsules—5 mg.

Tablets and Elixir Indications: FDA has evaluated this drug as Effective as an adjunct in the therapy of the indications listed below under SEQUELS.

***INDICATIONS FOR ARTANE SEQUELS:**
Based on a review of this drug in sustained release form by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows: Probably effective as an adjunct in the therapy of all forms of parkinsonism (postencephalitic, arteriosclerotic, and idiopathic) and for use in the prevention or control of extrapyramidal disorders due to central nervous system drugs such as reserpine and phenothiazines.

WARNING:
Patients to be treated should have a gonioscope evaluation and close monitoring of intraocular pressures at regular periodic intervals.

Precautions: Patients with cardiac, liver or kidney disorders or with hypertension should be maintained under close observation. In long-term therapy, take care to avoid allergic and other untoward reactions. Use with caution in patients with glaucoma, obstructive disease of the gastrointestinal or genitourinary tracts and in elderly males with possible prostatic hypertrophy. Geriatric patients require strict dosage regulation. Incipient glaucoma may be precipitated.

Adverse Reactions: Such effects as dryness of mouth, blurring of vision, dizziness, nausea or nervousness will be experienced by 30 to 50 per cent of patients. (These tend to lessen and can often be controlled by adjusting dosage.) Isolated instances of suppurative parotitis, skin rashes, dilation of the colon, paralytic ileus, delusions, hallucinations and paranoia (1 doubtful case) have been reported. Patients with arteriosclerosis or with a history of idiosyncrasy to drugs may exhibit mental confusion, agitation, disturbed behavior, or nausea and vomiting. If a severe reaction occurs, discontinue drug for a few days, then resume at lower dosage. Psychiatric disturbances can result from overdosage to sustain euphoria. Side effects of any atropine-like drugs include constipation, drowsiness, urinary hesitancy or retention, tachycardia, dilation of the pupil, increased intraocular tension, weakness, vomiting and headache.

†Lime-mint flavored, with 0.08% methylparaben, 0.02% propylparaben, and 5% alcohol as preservatives.

*This drug in sustained release form has been evaluated as probably effective. See Brief Summary.

Lederle LEDERLE LABORATORIES, A Division of American Cyanamid Company, Pearl River, New York 10965

716-3
A53

Today, she managed a smile

(Not long ago, she couldn't stop sobbing)

Before he sees that first positive response—however hesitant and tentative—the physician may have to bring into play many different aspects of therapy. Establishing a therapeutic relationship may be the first difficulty as well as the first necessity. Psychotherapy, family and community support, occupational and social counseling, and drug therapy may all have to be enlisted.

The characteristically rapid energizing action of VIVACTIL may help establish early therapeutic rapport by lessening the patient's lethargy—often during the first week of medication. VIVACTIL helps elevate mood, usually within the third or fourth week of treatment.

Characteristically, the drug has no sedating or tranquilizing properties. (Symptoms such as anxiety or agitation may be aggravated.)

Dosage of VIVACTIL must be individualized, and patients should be under close medical supervision. For many adult patients with clinically significant depression, 10 mg t.i.d. may provide control of symptoms. Others may require as little as 15 mg or as much as 60 mg a day. In elderly patients and adolescents, lower dosages are recommended.

In depression,

TABLETS, 5 mg and 10 mg

Vivactil®

(Protriptyline HCl | MSD) helps establish early therapeutic rapport

Contraindications: Known hypersensitivity; acute recovery phase following myocardial infarction. Not recommended for use in children. Should not be given concomitantly with an MAOI; hyperpyretic crises, severe convulsions, and deaths have occurred in patients receiving tricyclic antidepressant and MAOI drugs simultaneously. When it is desired to substitute protriptyline HCl for an MAOI, a minimum of 14 days should be allowed to elapse after the latter is discontinued. Protriptyline HCl should then be initiated cautiously with gradual increase in dosage until optimum response is achieved.

Warnings: May block the antihypertensive effect of guanethidine or similarly acting compounds. May impair mental and/or physical abilities required for the performance of hazardous tasks, such as operating machinery or driving a motor vehicle. Should be used with caution in patients with a history of seizures and, because of its autonomic activity, in patients with a tendency to urinary retention or increased intraocular tension.

Tachycardia and postural hypotension may occur more frequently than with other antidepressant drugs. Should be used with caution in elderly patients and patients with cardiovascular disorders; such patients should be observed closely because of the tendency of the drug to produce tachycardia, hypotension, arrhythmias, and prolongation of the conduction time. Myocardial infarction and stroke have occurred with drugs of this class. On rare occasions, hyperthyroid patients or those receiving thyroid medication may develop arrhythmias when this drug is given.

Usage in Children: Not recommended for use in children because safety and effectiveness in the pediatric age group have not been established.

Usage in Pregnancy: Safe use in pregnancy and lactation has not been established; therefore, use in pregnant women, nursing mothers, or women who may become pregnant requires that possible benefits be weighed against possible hazards to mother and child.

Precautions: When protriptyline HCl is used to treat the depressive component of schizophrenia, psychotic symptoms may be aggravated; likewise, in manic-depressive psychosis, depressed patients may experience a shift toward the manic phase; paranoid delusions, with or without associated hostility, may be exaggerated. In any of these circumstances, it may be advisable to reduce the dose of protriptyline HCl or to use a major tranquilizing drug, such as perphenazine, concurrently. Symptoms, such as anxiety or agitation, may be aggravated in overactive or agitated patients.

When given with anticholinergic agents or sympathomimetic drugs, close supervision and careful adjustment of dosages are required. In healthy test subjects, maximum therapeutic doses significantly potentiated the peripheral circulatory effects of intravenous norepinephrine and epinephrine (manifested by undue increase in systolic and diastolic blood pressure and decrease in pulse rate). May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains during treatment and until significant remission occurs; this type of patient should not have easy access to large quantities of the drug. Concurrent administration with electroshock therapy may increase the hazards of therapy; such treatment should be limited to patients for whom it is essential. Discontinue the drug several days before elective surgery, if possible.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions which have not been reported with this specific drug. However, the pharmacologic similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when protriptyline HCl is administered. Protriptyline HCl is more likely to aggravate agitation and anxiety and produce cardiovascular reactions such as tachycardia and hypotension.

Cardiovascular: hypotension, hypertension, tachycardia, palpitation, arrhythmias.

CNS and Neuromuscular: confusional states (especially in the elderly); disorientation; delusions; hallucinations; anxiety; agitation; restlessness; insomnia; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremor; seizures.

Anticholinergic: dry mouth and, rarely, associated sublingual adenitis; blurred vision; disturbance of accommodation; mydriasis; constipation; urinary retention; dilatation of the urinary tract.

Other: skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight), edema (general, or of face and tongue), nausea, vomiting, epigastric distress, anorexia, peculiar taste, stomatitis, parotid swelling, impotence, jaundice (simulating obstructive), drowsiness, dizziness, weakness, fatigue, headache, perspiration, weight gain or loss, urinary frequency.

Withdrawal Symptoms: In an occasional patient, abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

The following adverse reactions have been reported less frequently with the class of antidepressant agent to which protriptyline HCl belongs: myocardial infarction, heart block, stroke, panic, nightmares, alteration in EEG patterns, hypomania, exacerbation of psychosis, extrapyramidal symptoms, tinnitus, paralytic ileus, delayed micturition, drug fever, bone-marrow depression, agranulocytosis, eosinophilia, purpura, thrombocytopenia, diarrhea, abdominal cramps, black tongue, testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, altered liver function, flushing, nocturia, alopecia.

Supplied: Tablets, containing 5 mg and 10 mg protriptyline HCl each, in single-unit packages of 100 and bottles of 100 and 1000.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486

MSD
MERCK SHARP DOHME

addendum

MSD 26 5 mg (orange)

MSD 47 10 mg (yellow)

The usual regimen for adults is 15 to 40 mg a day divided into three or four doses. Dosage may be increased to 60 mg a day if necessary.

In elderly and adolescent patients, lower dosages are recommended; initially, a regimen of 5 mg t.i.d. is suggested with adjustment as necessary to the required amount. In elderly patients, the cardiovascular system must be monitored closely when the daily dose exceeds 20 mg.

Because VIVACTIL (Protriptyline HCl, MSD) characteristically is a nonsedating tricyclic antidepressant, activating and energizing in effect, the last dose of the day should be given no later than mid-afternoon to avoid insomnia. Required increases should be added to the morning dose.

When necessary to increase dosage, it should be done gradually. After satisfactory improvement has been achieved, dosage should be reduced to the smallest amount that will maintain relief of symptoms. Maintenance therapy should be continued for at least three months after satisfactory improvement occurs.

(*Usage in Children:* In view of the lack of experience in children, this drug is not recommended for patients under 12 years of age.)

Three new JIS publications:

THE TREATMENT OF DRUG ABUSE — Programs, Problems, Prospects

AUTHORS: Raymond Glasscote, Jerome H. Jaffe, James N. Sussex, John Ball, Leon Brill

What can a community that wants to do something about a perceived drug abuse problem reasonably expect to get for its efforts? That is the question the authors undertook to answer through a field study that consisted of visits to nine programs operating more than forty facilities and components for various categories of persons who use drugs — mainly narcotics. They conclude that no single one of the presently available approaches can be expected to be successful with more than a small percentage of the drug-abusing population, and all approaches combined will have an "undoubtedly limited" effect. Rather than take a position for or against any particular treatment approach, they discuss the positive and negative features of each. A wealth of significant detail is provided about a number of well-known programs, with an objectivity that has been altogether too rare in this field. The authors set forth one reasonable sequence that might be followed by communities seeking to establish various drug treatment resources that will be appropriate for their particular needs.

CHILDREN AND MENTAL HEALTH CENTERS — Programs, Problems, Prospects

AUTHORS: Raymond Glasscote, Michael Fishman, Meyer Sonis

This tenth in a series of Joint Information Service field studies of mental health programs focuses on the efforts of federally assisted mental health centers to meet the needs of children and adolescents, both through direct treatment services and through consultation programs that seek to enhance the competence of numerous kinds of persons who have an important influence on the lives of children. Based on visits by the authors and consultants to eight outstanding programs, this volume also incorporates the findings of a questionnaire survey to all federally supported community mental health centers. It also provides a full but concise history of treatment efforts for young people in this country, and, most important, it sets forth a hypothetical comprehensive program that is broader than any single program presently operating in the United States.

ELEVEN INDICES

PREPARED BY Charles Kanno

This "aid in reviewing state and local mental health and hospital programs" is a successor to the long-established *Fifteen Indices*, published by the Joint Information Service since 1956. The new version eliminates some of the indices that are no longer applicable in view of changes in the mental health delivery system, adds new ones, and uses a different reporting form for others. It provides state-by-state data for expenditures for mental health programs, hospitalization rates, rehabilitated mental illness clients, percent of population living in community mental health center catchment areas, and so on. In addition, a separate profile is provided for each state, indicating its performance against the national averages.

A significant response to the major clinical and economic problems which face community-oriented psychiatrists.

Psychiatric Institutes of America will enable you to develop and control your own programs through ownership of a new fully-accredited psychiatric hospital in your community. And will make available in-depth clinical and administrative support...so you can provide patients with the kind of treatment you want them to have.

PIA will arrange financing and will provide for design, construction, hospital staffing and administration. Six facilities are now in operation. Others are under construction or development. For more information contact

Edward S. Fleming, MD, President
Psychiatric Institutes of America

"I can't face life anymore."

Before Peter G. came to you his boss was treating him. He told him to "take the day off and try to snap out of it."

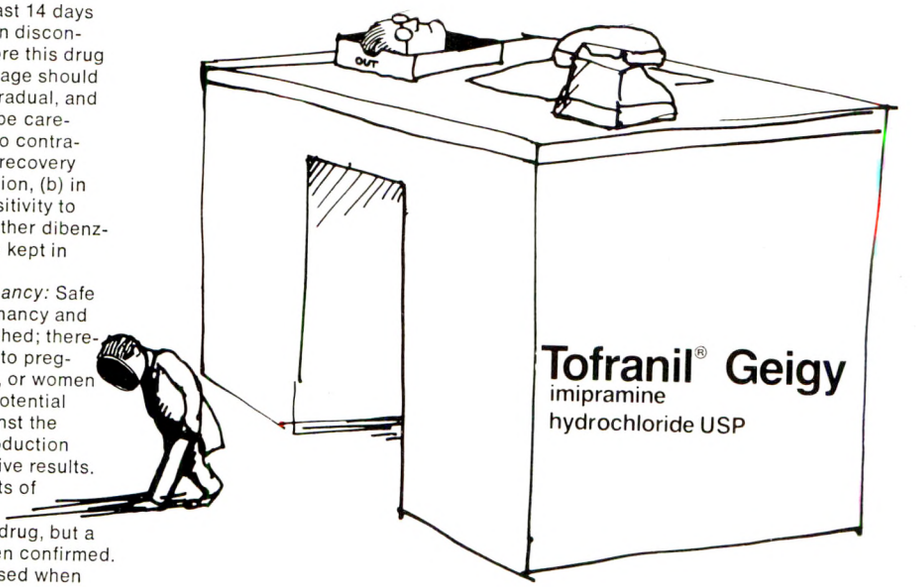
But Peter is seriously depressed.

He needs more than a day off. He needs psychotherapy. By usually relieving the symptoms of depression, Tofranil may make the patient more responsive to your psychotherapy.

Tofranil may be especially helpful in treating depressions where an endogenous component is suspected.

In helping to relieve depression, usually without oversedating a patient, Tofranil may be beneficial to patients who continue or return to work. This aspect of Tofranil may also be a consideration in selecting medication for patients whose depressive symptoms include fatigue and psychomotor retardation.

Since sedation may occur in some persons, patients, especially the elderly, should be cautioned against driving a car or operating dangerous machinery.



Please read the prescribing information for details of usage, precautions, warnings, contraindications, adverse experiences, and dosage recommendations. A summary of this information appears on the following page.

Geigy

Tofranil®
imipramine hydrochloride USP

Tofranil® imipramine hydrochloride USP

When depression comes to mind...

Contraindications: The concomitant use of this agent and monoamine oxidase inhibiting (M.A.O.I.) compounds is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur. Potentiation of adverse effects can be serious or even fatal. An interval of at least 14 days after M.A.O.I. therapy has been discontinued should be allowed before this drug may be substituted. Initial dosage should be low, increases should be gradual, and the patient's progress should be carefully observed. The drug is also contraindicated (a) during the acute recovery period after myocardial infarction, (b) in patients with known hypersensitivity to the drug. Cross-sensitivity to other dibenzazepine compounds should be kept in mind.

Warnings: *Usage in Pregnancy:* Safe use of imipramine during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women of childbearing potential, the potential benefits must be weighed against the possible hazards. Animal reproduction studies have yielded inconclusive results. There have been clinical reports of congenital malformation associated with the use of this drug, but a causal relationship has not been confirmed.

Extreme caution should be used when this drug is given to:

- patients with cardiovascular disease because of the possibility of conduction defects, arrhythmias, myocardial infarction, strokes and tachycardia;
- patients with increased intraocular pressure, history of urinary retention, or history of narrow-angle glaucoma because of the drug's anticholinergic properties;
- hyperthyroid patients or those on thyroid medication because of the possibility of cardiovascular toxicity;
- patients with a history of seizure disorder because this drug has been shown to lower the seizure threshold;
- patients receiving guanethidine or similar agents since imipramine may block the pharmacologic effects of these drugs.

Usage in Children: Pending evaluation of results from clinical trials in children, the drug is not recommended for use in patients under twelve years of age.

Since the drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as operating an automobile or machinery, the patient should be cautioned accordingly.

Precautions: Because of the possibility of suicide in seriously depressed patients, careful supervision during the early phase of treatment is necessary and hospitalization may be required. Prescriptions should be written for the smallest amount feasible.

Hypomanic or manic episodes may occur, particularly in patients with cyclic disorders. Such reactions may necessitate discontinuation of the drug. If needed, imipramine may be resumed in lower dosage when these episodes are relieved. Administration of a tranquilizer may be useful in controlling such episodes.

Prior to elective surgery, imipramine should be discontinued for as long as the clinical situation will allow.

An activation of the psychosis may occasionally be observed in schizophrenic patients and may require reduction of dosage and the addition of a phenothiazine.

In occasional susceptible patients or in those receiving anticholinergic drugs (including antiparkinsonism agents) in addition, the atropine-like effects may become more pronounced (e.g. paralytic ileus). Close supervision and careful adjustment of dosage is required when this drug is administered concomitantly with anticholinergic or sympathomimetic drugs.

Patients should be warned that the concomitant use of alcoholic beverages may be associated with exaggerated effects.

Both elevation and lowering of blood sugar levels have been reported.

Concurrent administration of imipramine with electroshock therapy may increase the hazards; such treatment should be limited to those patients for whom it is essential.

Adverse Reactions: *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke, falls.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurological: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alterations in EEG patterns; tinnitus.

Anticholinergic: Dry mouth, and, rarely, associated sublingual adenitis; blurred vision, disturbances of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue), drug fever, cross-sensitivity with desipramine.

Hematologic: Bone marrow depression including agranulocytosis; eosinophilia; purpura; thrombocytopenia. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathological neutrophil depression.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea; peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine: Gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency; drowsiness, dizziness, weakness and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache and malaise.

How Supplied: Round tablets of 25 and 50 mg.; triangular tablets of 10 mg. for geriatric and adolescent use; and ampuls, each containing 25 mg. in 2 cc. for I.M. administration. (B)98-146-850-J (7/71)

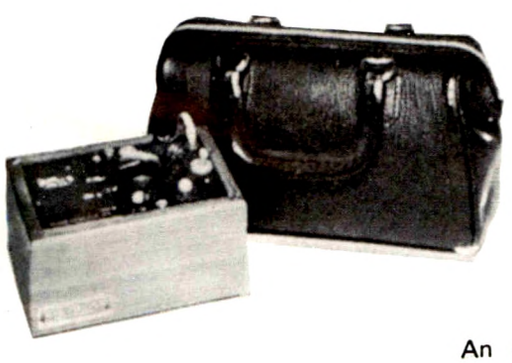
MORE THAN 30 YEARS...

have proven the dependability and effectiveness of REITER ELECTROSTIMULATORS in psychiatry! Research and constant improvements to meet the standards of improved techniques have kept Reiter instruments

THE WORLD'S MOST ACCEPTED ELECTROSTIMULATORS

The Two Popular Models— **PORTABLE FOR OFFICE AND CLINIC**



The Reiter MODEL SOS—THE ONE INSTRUMENT FOR ALL ESTABLISHED TECHNIQUES, provides the fullest range of safest therapies. For painless, gentle stimulation of the conscious patient to relieve anxiety, depression, etc. Maximum safety, no additives—patient conscious and cooperating with therapy.

The SOS has also been used universally for Convulsive Therapy, Non-Convulsive Therapies, Electro-Sleep Therapy, Focal Treatment, Mono-Polar Treatment, Barbiturate Coma (and other respiratory problems), Mild Sedac, Deep Sedac Therapy, Pre-Convulsive Sedac, Post-Convulsive Sedac, Neurological Conditions, and Measurement Procedures.

Available with this redesigned model, on request, the following special-purpose electrodes —a Multi-Polar "Collar" type for Sleep Therapy, a "Horseshoe" assembly for quicker, surer application with one hand at last moment before ECT treatment, and a "Unilateral" type assembly.

Also built-in on request, an **automatic switch** for quicker build up to therapeutic ranges of Sedac.

SPECIAL MODEL SOS available without unidirectional convulsive current.

The Reiter Compact MOL-AC II—The smallest, lightest, least expensive and most reliable, clinically proven A.C. shock therapy instrument. Less confusion than from similar A.C. equipment. Now available with redesigned, improved panel. This compact instrument is only 3 x 5 inches, weighs but 3 lbs., yet provides full positive control of glisando effect over entire voltage range, as well as a positive manual control of time. There are NO complicated settings of dials, NO waiting for resetting of time devices, no warm-up delays.

An officially approved, extremely durable instrument which has earned world-wide professional acceptance, the MOL-AC II is economically priced with a fine, genuine leather physician's bag included.

Other Models Still Available: The CW47, original therapeutic cerebral stimulator with only 3 of the 9 treatment current selections available on Model SOS.

when
extrapyramidal
symptoms upset
phenothiazine
therapy

TABLETS: 0.5 mg, 1 mg, and 2 mg
INJECTION: 1.0 mg/cc

COGENTIN®
(BENZTROPINE MESYLATE | MSD)

helps keep productive therapy from becoming counterproductive

- Helps relieve rigidity and tremor
- Provides long duration of action
- Frequently permits continuation of the phenothiazine without change of dosage

Contraindications: Children under three years of age; use cautiously in older children.

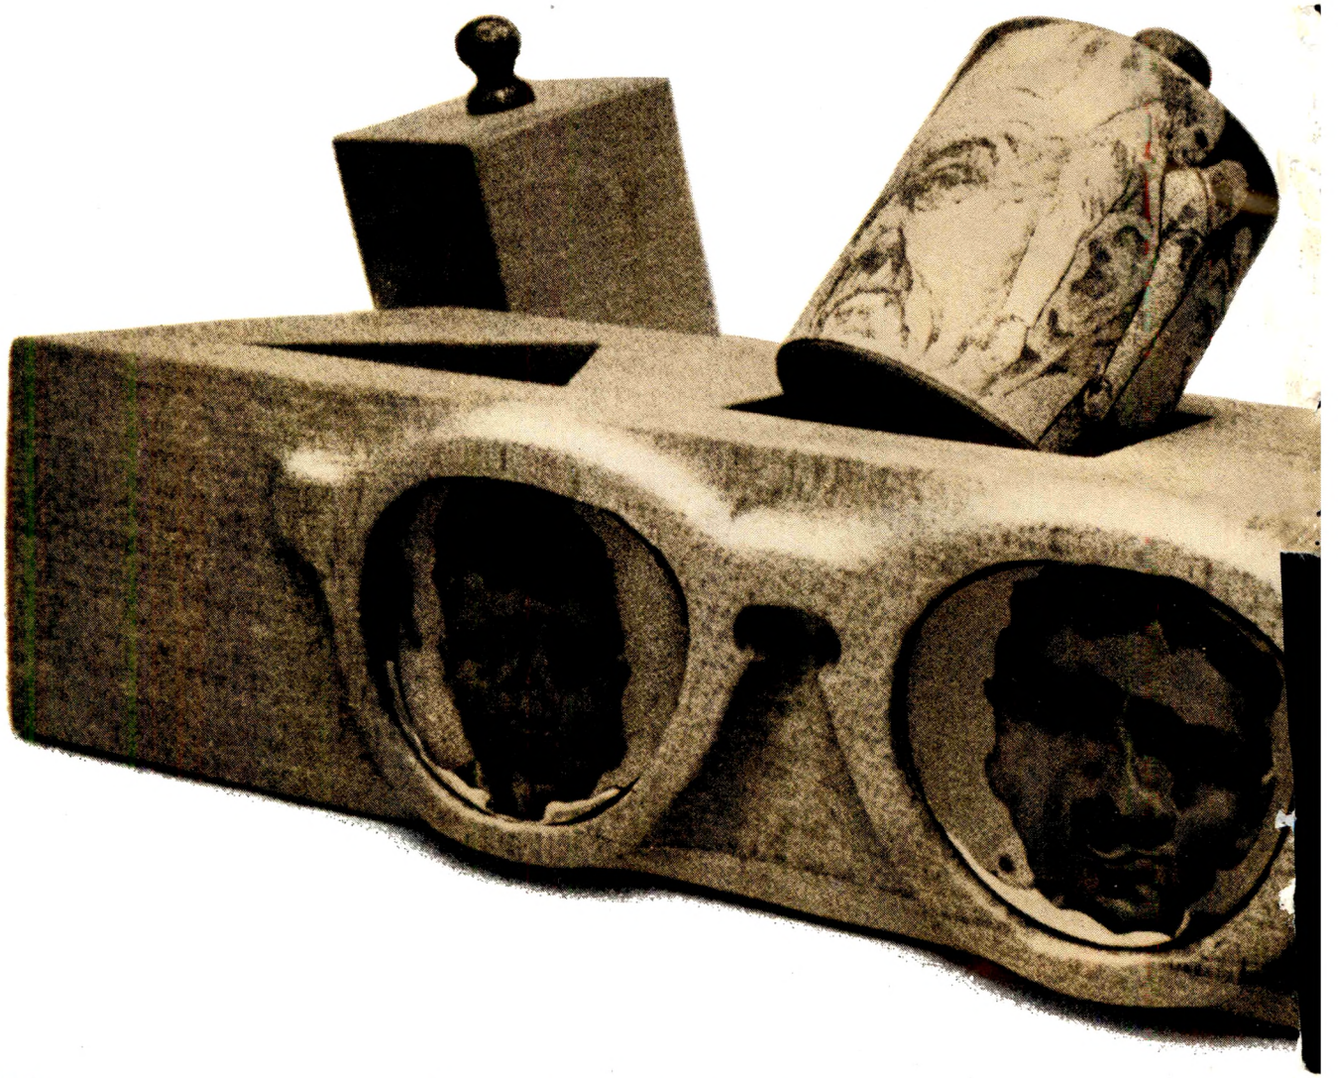
Warnings: Safe use in pregnancy not established. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle.

Precautions: Because of cumulative action, continued supervision is advisable. Closely observe patients with tendencies to tachycardia or hypotension and those with prostatic hypertrophy. Dysuria may occur, but rarely becomes a problem. Large doses may cause complaints of weakness and inability to move particular muscle groups, requiring dosage adjustment.

Mental confusion and excitement may occur with large doses, or in susceptible patients; visual hallucinations reported occasionally. May intensify mental symptoms when used to treat extrapyramidal disorders due to CNS drugs, such as reserpine and phenothiazines, in patients with mental disorders; in such patients, increased doses of antiparkinsonian drugs can precipitate toxic psychosis; observe patients carefully, especially at the beginning of treatment or if dosage is increased. Masking action on possible development of permanent extrapyramidal symptoms with prolonged phenothiazine therapy has not been investigated. Patients with a poor mental outlook are usually poor candidates for therapy.

May produce anhidrosis; give with caution during hot weather, especially to the old, the chronically ill, the alcoholic, those who have central nervous system disease, those who do manual labor in a hot environment, and those with disturbances in sweating. If anhidrosis appears, reduce dosage so that ability to maintain body heat equilibrium is not impaired. Occurrence of glaucoma is a possibility; probably should not be used in angle-closure glaucoma.

Large doses generally cannot be tolerated by older patients, thin patients, or patients with arteriosclerotic parkinsonism. Do not terminate other antiparkinsonism agents abruptly; reduce gradually. In drug-induced parkinsonism, closely observe patients for severe reactions, and temporarily discontinue COGENTIN (Benztropine Mesylate, MSD) if they appear; do not extend therapy longer than necessary to counteract the extrapyramidal disorders; although the psychotropic drug frequently can be continued without change of dosage, a decrease might be indicated.



Adverse Reactions: Adverse reactions may be anticholinergic and/or antihistaminic. Dry mouth, blurred vision, nausea, nervousness may develop. If dry mouth causes difficulty in swallowing or speaking, or loss of appetite and weight, reduce dosage, or discontinue drug temporarily. Vomiting occurs infrequently and may be controlled by temporary discontinuation, followed by resumption at a lower dosage. Constipation, numbness of the fingers, listlessness, and depression may develop. Occasionally, an allergic reaction, e.g., skin rash, develops; sometimes this can be controlled by reducing dosage, but occasionally requires discontinuation.

Supplied: Tablets in three strengths: 0.5 mg and 1 mg benztropine mesylate, in bottles of 100, and 2 mg benztropine mesylate, in bottles of 100 and 1000. Injection, containing 1.0 mg benztropine mesylate and 9.0 mg sodium chloride per cc, in 2-cc ampuls.

For more detailed information, consult your MSD representative or see the Direction Circular. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486

MSD MERCK SHARP & DOHME

H lp im,rov you. d r d patients' ability to cope.

In Brief:

Actions: Norpramin® (desipramine hydrochloride) is an antidepressant drug of the tricyclic type. It has been found in some studies to have a more rapid onset of action than imipramine; antidepressant efficacy is similar though potency on a weight basis may be less. The earliest manifestations consist mainly of an increase in psychomotor activity. Full treatment benefit is seldom attained before the end of the second week.

Indications: Norpramin® (desipramine hydrochloride) is indicated for the relief of depressive symptoms. Endogenous depressions are more likely to be alleviated than others.

Contraindications: Desipramine hydrochloride should not be given within two weeks of treatment with a monoamine oxidase inhibitor. Contraindications include the acute recovery period following myocardial infarction and hypersensitivity to the drug. Cross sensitivity with other dibenzazepines is a possibility.

Warnings: 1. Extreme caution should be used in patients: (a) with cardiovascular disease, (b) with a history of urinary retention or glaucoma, (c) with thyroid disease or those on thyroid medication, (d) with a history of seizure disorder. 2. This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. 3. *Use in Pregnancy:* Safe use during pregnancy and lactation has not been established. 4. *Use in Children:* Norpramin® (desipramine hydrochloride) is not recommended for use in children. 5. This drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. Therefore, the patient should be cautioned accordingly.

Precautions: This drug should be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with drugs of this class. It should be kept out of reach of children. Reduce dosage, or alter treatment, if serious adverse effects occur. Norpramin® (desipramine hydrochloride) therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates and may cause exacerbation of psychosis in schizophrenic patients. Close supervision an careful adjustment of dosage are required wh this drug is given along with anticholinergic sympathomimetic drugs. While taking this drug, response to alcoholic beverages may be exaggerated. There is limited clinical experience in th concurrent administration of ECT and antid pressant drugs; thus, one should consider t possibility of increased risk relative to benefits. Discontinue as soon as possible prior to elective surgery because of possible cardiovascular effects. Hypertensive episodes have bee observed during surgery in patients on desipra mine hydrochloride. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therap the drug should be discontinued if there is ne tropenia.

Adverse Reactions: *Cardiovascular:* hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke. *Psychiatric:* confusional states (especially

Coping with Depression

The ability to cope with depressive illness, for the patient and to some degree for the physician, largely depends on hope—a crutch that is usually lacking in the depressed patient. To the depressed patient all the good things of life are bleak, black, or unattainable; all that is bad has been happening or will happen. Helping such a patient to cope with life again, to overcome the incapacitating moods, outlooks, and fears which characterize depression, can be a most rewarding experience for the physician.

Although Norpramin® (desipramine hydrochloride) is relatively rapid-acting, the patient should be told that he will not feel better immediately but that he will gradually become his old self again. A minor tranquilizer in appropriate dosage may be used with Norpramin temporarily if anxiety due to depression is present; a phenothiazine may be used similarly if agitation is severe.

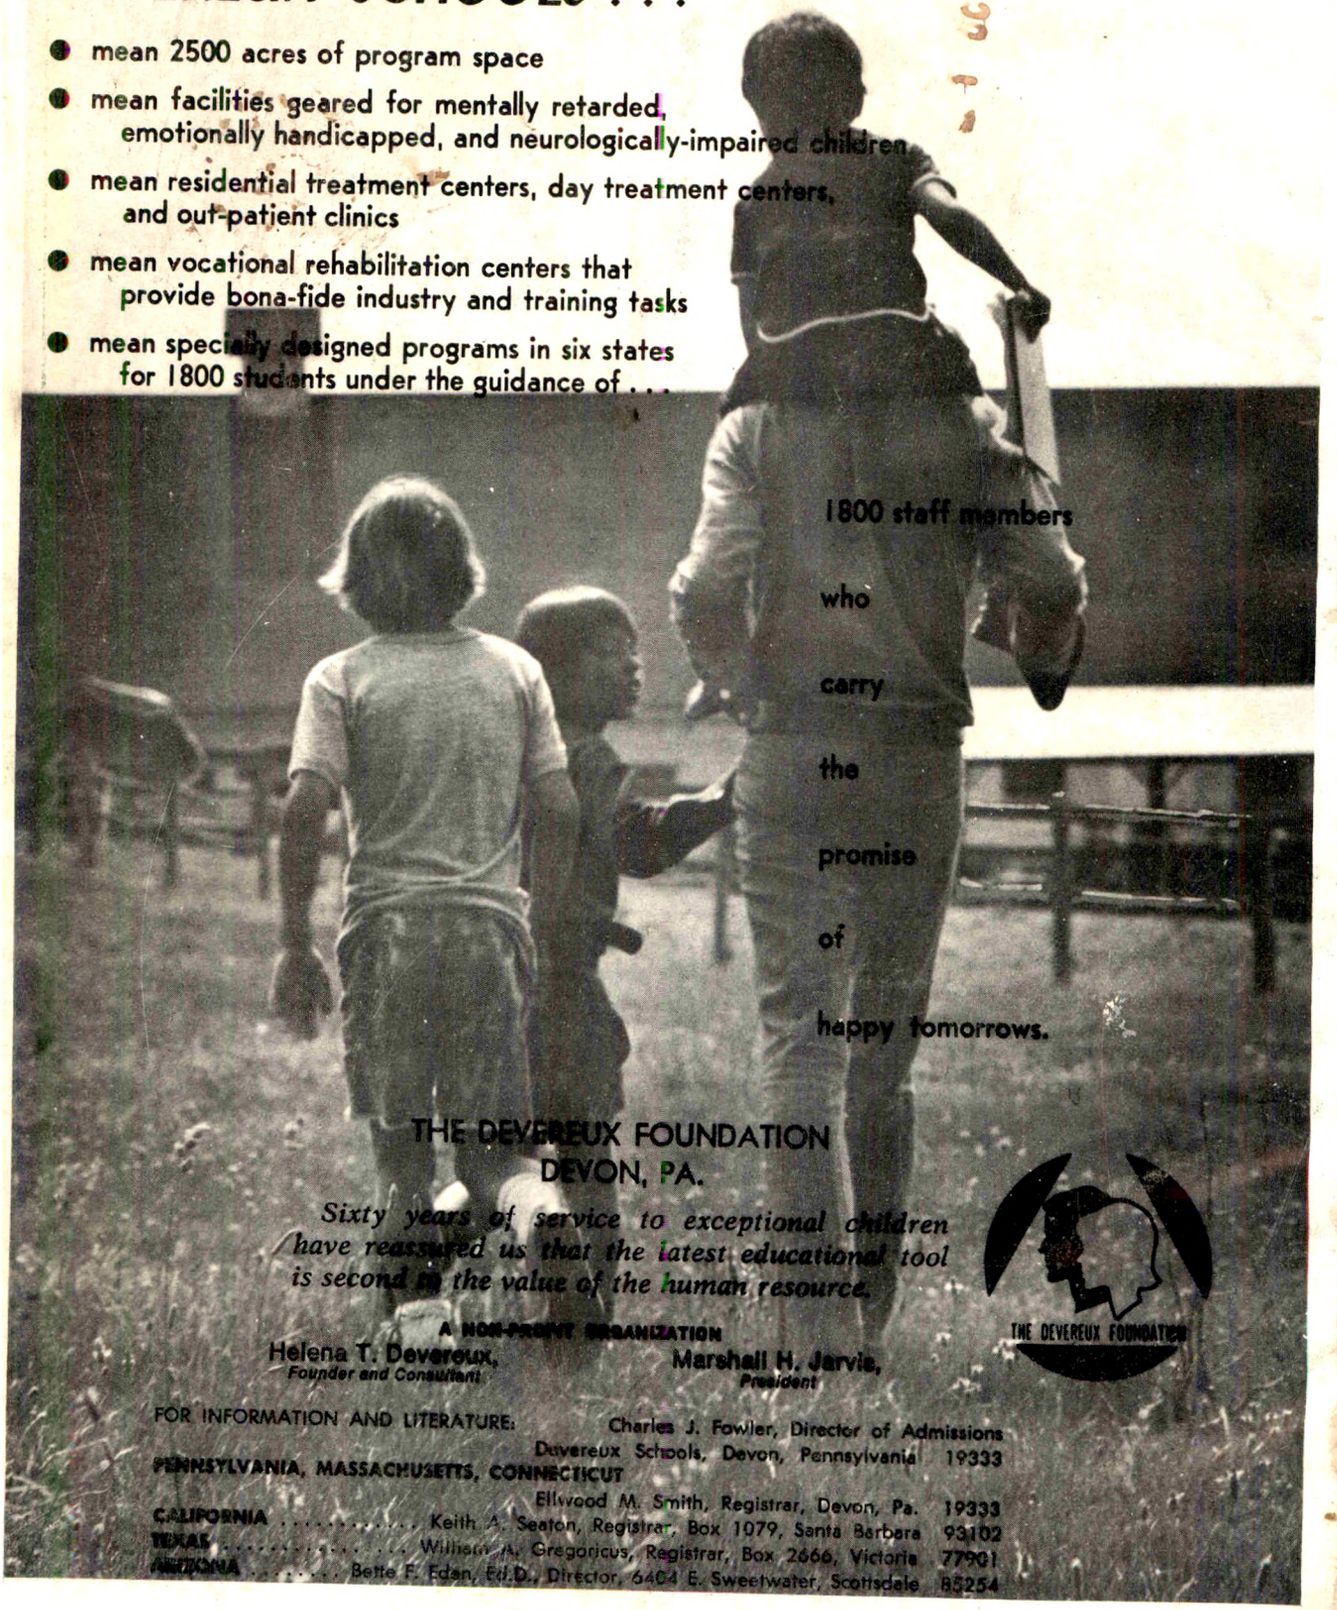
Frequently, Norpramin and your own understanding of the patient are all that is necessary.

Norpramin®
(desipramine hydrochloride)
helps the depressed cope with life again.

in the elderly), hallucinations, disorientation, delusions; anxiety, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis. *Neurological:* paresthesias of extremities; incoordination, ataxia, tremors, peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus. *Anticholinergic:* dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, hypotonic bladder. *Allergic:* skin rash, petechiae, urticaria, itching, photosensitization, edema (of face and tongue or general), drug fever. *Hematologic:* agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue. *Endocrine:* gynecomastia; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels. *Other:* jaundice (simulating obstructive), altered liver function; weight gain or loss; perspiration, flushing; urinary frequency, nocturia; parotid swelling; drowsiness, dizziness, weakness and fatigue, headache; alopecia. *Withdrawal Symptoms:* Though not indicative of addiction, abrupt cessation after prolonged therapy may produce nausea, headache and malaise.

Dosage and Administration: *The usual adult dose:* 50 mg. three times daily; increase if necessary after 7 to 10 days to maximum of 200 mg. daily. Dosages above 200 mg. per day are not recommended. *Maintenance:* At a lower dose adequate to maintain remission. *Adolescent and geriatric patient dose:* 25 to 50 mg. daily if necessary.

Overdosage: There is no specific antidote for desipramine, nor are there specific phenomena of diagnostic value characterizing poisoning by the drug. The principles of management of coma and shock by means of the mechanical respirator, cardiac pacemaker, monitoring of central venous pressure and regulation of fluid- and acid-base balance are well known in most medical centers. If heart failure is imminent, digitalize promptly.



How Supplied: Norpramin® (desipramine hydrochloride) *25 mg.*, sugar coated tablets, yellow, in bottles of 50, 500 and 1000 tablets. Norpramin® (desipramine hydrochloride) *50 mg.*, sugar coated tablets, light green, in bottles of 50, 250 and 1000 tablets.
